ABSTRACT

We present a multiwavelength study of the unidentified Fermi object, 3FGL J0212.1+5320. Within the 95\% error ellipse, Chandra detects a bright X-ray source (i.e., \(F_{\text{0.5–7 keV}} = 1.4 \times 10^{-12} \text{ cm}^{-2} \text{ s}^{-1}\)) that has a low-mass optical counterpart (\(M < 0.4 M_\odot\) and \(T \sim 6000 \text{ K}\)). A clear ellipsoidal modulation is shown in optical/infrared at 20.87 hr. The gamma-ray properties of 3FGL J0212.1+5320 are all consistent with that of a millisecond pulsar (MSP), suggesting that it is a \(\gamma\)-ray redback (RB) MSP binary with a low-mass companion filling \(\geq 64\%\) of the Roche lobe. If confirmed, it will be an RB binary with one of the longest orbital periods known. Spectroscopic data taken in 2015 from the Lijiang observatory show no evidence of strong emission lines, revealing that the accretion is currently inactive (the rotation-powered pulsar state). This is consistent with the low X-ray luminosities (\(L_X \approx 10^{32} \text{ erg \, s}^{-1}\)) and the possible X-ray modulation seen by Chandra and Swift. Considering that the X-ray luminosity and the high X-ray-to-\(\gamma\)-ray flux ratio (8\%) are both comparable to those of the two known \(\gamma\)-ray transitional MSPs, we suspect that 3FGL J0212.1+5320 could be a potential target to search for future transition to the accretion active state.

Key words: binaries: close – gamma-rays: stars – pulsars: general – X-rays: binaries

1. INTRODUCTION

Progenitors of millisecond pulsars (MSPs), though not yet fully understood, are believed to be neutron stars in low-mass X-ray binaries (LMXBs). According to the recycling scenario (Alpar et al. 1982), the neutron stars are spun up through accretion from the late-type companions (if any) to ultimately evolve into MSPs. Through the so-called LMXB Case A channel (Tauris 2011), a compact binary (i.e., orbital period \(< 1 \text{ day}\)) consisting of an MSP and a very low-mass companion (which was stripped by the neutron star and/or partially “evaporated” by the energetic pulsar wind/\(\gamma\)-rays; Chen et al. 2013) remains at the very end phase of such an evolution, known as black widow (BW; companion mass: \(< 0.1 M_\odot\)) or redback (RB; companion mass: \(-0.1\)–0.4 \(M_\odot\)) binaries. A few RBs, known as transitional MSPs (tMSPs), have already shown remarkable transition(s) between the LMXB state and the radio pulsar state in optical, X-rays, and/or \(\gamma\)-rays (i.e., M28I, Papitto et al. 2013; PSR J1023+0038, Archibald et al. 2009; Patruno et al. 2014; PSR J1227–4853, Roy et al. 2015), clearly indicating the close relationship between LMXBs and radio MSPs. BW/RBs are interesting objects, not to mention the fascinating theoretical interpretation of multiwavelength observations for individual studies (e.g., the keV-to-GeV emission models of PSR J1023+0038 in different decades; Li et al. 2014; Papitto & Torres 2015). They also provide crucial information on the long-term accretion history. In particular, BWs are the key to uncovering how the companions are finally eliminated, after which isolated MSPs are formed (van den Heuvel & van Paradijs 1988).

As MSPs are powerful \(\gamma\)-ray sources with strong GeV magnetospheric radiations (e.g., from the outer gap, the slot gap, or the polar cap; Ruderman & Sutherland 1975; Cheng et al. 1986; Muslimov & Harding 2003) and/or the inverse-Compton \(\gamma\)-ray emissions of the pulsar wind nebulae when the accretion is active (Li et al. 2014; Takata et al. 2014), many of them should have been detected by Fermi-LAT as a class of unidentified Fermi object (UFO), the second-largest population detected by Fermi-LAT (Acero et al. 2015). Although not all the UFOs are MSPs (in fact, many of them are thought to be active galactic nuclei, the largest source class in the catalog), good BW/RB candidates can be selected based on the \(\gamma\)-ray spectral curvatures and the \(\gamma\)-ray variabilities (Kong et al. 2012, 2014; Ray et al. 2012; Hui et al. 2015b) and their pulsar natures confirmed by detecting the radio/\(\gamma\)-ray pulsations. Thanks to the Fermi Pulsar Search Consortium, a great success has been achieved in discovering new pulsars through “blind” searches for coherent pulsations in radio and \(\gamma\)-rays (Ray et al. 2012), and the known BW and RB populations have been greatly extended in recent years.

Alternatively, multiwavelength studies of UFOs are the secondary way to search for BW/RB MSP candidates. In most of the cases, X-ray follow-ups are the key to narrowing down the source location, allowing identification of the optical counterparts. Once the optical counterpart is identified, time-series optical observations can test the BW/RB identity by searching for the orbital modulation on timescales of hours produced by pulsar irradiation on the companion and/or ellipsoidal variation. Through this multiwavelength technique, several UFOs, for example, 2FGL J1311.7–3429/PSR J1311–3430 (Pletsch et al. 2012), 1FGL J1417.7–4407/PSR J1417–4402 (not a canonical BW/RB system; Strader et al. 2015; Camilo et al. 2016), and 1FGL J2339.7–0531/PSR J2339–0533 (Kong et al. 2012; Pletsch & Clark 2015) have been identified as MSP binaries, and some of them have been confirmed by the detection of millisecond radio/\(\gamma\)-ray pulsations, proving the validity of the method.

In this paper, we report the discovery of a \(\gamma\)-ray-emitting RB candidate, 3FGL J0212.1+5320. In the following sections, we
Table 1

X/γ-Ray Properties of Some Known RBs in the Pulsar State and 3FGL J0212.1+5320

| Name          | Spectral Curvature | Variability | \(F_{\gamma}^{\text{1.100 GeV}}\) (10\(^{-12}\) erg cm\(^{-2}\) s\(^{-1}\)) | \(\Gamma_X\) | \(F_{\gamma}^{\text{5–7 keV}}\) (10\(^{-12}\) erg cm\(^{-2}\) s\(^{-1}\)) | \(F_X/F_{\gamma}\) |
|---------------|---------------------|-------------|---------------------------------|-------------|---------------------------------|-------------------|
| PSR J2129−0429| 3.7                 | 60.3        | 1.1                             | 1.3         | 0.11                            | 0.10%             |

present multiwavelength studies using the optical imaging/spectroscopic data from the Lijiang (Fan et al. 2015), Lulin, and Michigan State University (MSU) observatories; the Chandra X-ray data; and the Fermi-LAT third source catalog (3FGL; Acero et al. 2015). Discussions will be given in the last section.

2. THE GAMMA-RAY PROPERTIES IN 3FGL

3FGL J0212.1+5320 is an unidentified bright γ-ray source (i.e., \(F_{\gamma} = (1.71 \pm 0.16) \times 10^{-11}\) erg cm\(^{-2}\) s\(^{-1}\) in 0.1–100 GeV, which is in the top 15% among the sources in 3FGL; Acero et al. 2015) that was first detected by Fermi-LAT in γ-rays in the Fermi-LAT first source catalog (1FGL; Abdo et al. 2010). It also later appears in 3FGL with a detection significance of 25σ.

Based on the second Fermi-LAT pulsar catalog (Abdo et al. 2013), the γ-ray properties of pulsars can be characterized by a low source variability and a curved γ-ray spectral shape. Although they are not necessary conditions, 3FGL J0212.1+5320 fulfills both of the criteria (Table 1), suggesting its possible pulsar nature in γ-rays. Similar to many other γ-ray pulsars that have been known in γ-rays over years (Abdo et al. 2010), 3FGL J0212.1+5320 can also be considered as a steady source with a small 3FGL variability index of 51.47 (i.e., for a source with a variability index larger than 72.44, there is less than 1% chance of being a steady source; Acero et al. 2015). In addition, the γ-ray spectrum of 3FGL J0212.1+5320 is probably more than a single power law, but rather with an extra curvature component (e.g., an exponential cutoff) as the spectral curve significance is 6.3σ in 3FGL, which is also another common feature among the pulsars detected in 3FGL (Acero et al. 2015). In fact, Saz Parkinson et al. (2016) and Mirabal et al. (2016) have found that 3FGL J0212.1+5320 is a strong MSP candidate, using statistical and machine-learning techniques.

3. SWIFT AND CHANDRA X-RAY OBSERVATIONS

As one of the survey targets in the Swift/XRT survey of Fermi unassociated sources (Stroh & Falcone 2013), 3FGL J0212.1+5320 has been observed twice by Swift/XRT in 2010 October (the observations are separated by 3 days with a total exposure time of 4.5 ks). Within the 95% Fermi error ellipse, a bright X-ray counterpart was detected and listed as 1SXPS J021210.6+532136 in the Swift/XRT point-source catalog (1SXPS; Evans et al. 2014). According to 1SXPS, the source is located at \(\alpha (J2000) = 02^h12^m10.6^s, \delta (J2000) = +53^\circ21'36''8\) (90% positional uncertainty: 3\(\sigma\)) with a mean count rate of \((2.26 \pm 0.26) \times 10^{-2}\) counts s\(^{-1}\). A moderate flux variability is seen between the two observations from \((2.61 \pm 0.32) \times 10^{-2}\) counts s\(^{-1}\) to \((3.13 \pm 0.41) \times 10^{-2}\) counts s\(^{-1}\) in 3 days (equivalent to a 2.9\(\sigma\) change). The X-ray spectrum could be described by an absorbed power law of \(N_H = 1.4 \pm 2.4 \times 10^{21}\) cm\(^{-2}\) (the Galactic column density \(N_H = 1.5 \times 10^{21}\) cm\(^{-2}\); Kalberla et al. 2005) and \(\Gamma_X = 1.0 \pm 0.5\) with an unabsorbed flux of \(F_{0.3–10\text{keV}} = 1.6 \pm 0.3 \times 10^{-12}\) erg cm\(^{-2}\) s\(^{-1}\) (\(W\text{-stat} = 57.98\) and \(\chi^2 = 63.02; \text{ dof} = 78\)). Alternatively, the spectrum could be fitted with an APEC thermal plasma model, but with an extremely high and poorly constrained plasma temperature (i.e., \(kT \sim 100\text{keV}\)). As the best-fit temperature is just too high to be physical, we do not further consider the APEC model in the following analyses.

Chandra has also observed the field of view once with ACIS for 30 ks in 2013 August (Obs ID: 14814; PI: Saz Parkinson), and 1SXPS J021210.6+532136 is clearly detected at \(\alpha (J2000) = 02^h12^m10.50^s, \delta (J2000) = +53^\circ21'38''9\) (90% positional uncertainty: 0\(\sigma\)) with a net count rate of \((9.03 \pm 0.17) \times 10^{-2}\) counts s\(^{-1}\) (0.5–7 keV). With a total number of
2685 photon counts, we binned the data to have at least 20 counts per bin and fitted the binned spectrum with an absorbed power law. The best-fit parameters are $N_H = (1.4 \pm 0.5) \times 10^{21} \text{cm}^{-2}$, $\Gamma_X = 1.3 \pm 0.1$, and $F_{0.5-7 \text{keV}} = (1.35 \pm 0.06) \times 10^{-12} \text{erg cm}^{-2} \text{s}^{-1}$ (or $F_{0.3-10 \text{keV}} = (1.89 \pm 0.08) \times 10^{-12} \text{erg cm}^{-2} \text{s}^{-1}$; $\chi^2 = 98.78$ and dof = 105), which are all consistent with those extracted from the Swift/XRT data and the Chandra spectral fitting by Szaz Parkinson et al. (2016). To examine the short-term variability seen by Swift/XRT, we extracted a 4000 s bin light curve with the Chandra/ACIS data, and a flux variability on an hourly timescale is clearly shown (Figure 1). To quantify the variability significance, we computed the $\chi^2$ value of the eight data bins with a flat light-curve model, which is $\chi^2 = 24.39$ (dof = 7), indicating that there is only a 0.1% chance that the variability is produced by random fluctuation.

4. OPTICAL DATA

At the Chandra X-ray position, we found a bright optical counterpart ($R = 14.23 \text{mag}$) in the USNO-B1.0 catalog (Monet et al. 2003), USNO-B1.0 1433-0078846, with an offset of 0\textdegree.2. The same source is also detected in the Two Micron All Sky Survey (2MASS; Skrutskie et al. 2006) and WISE (Wright et al. 2010) catalogs. Using the multi-epoch photometry table of WISE, a variability of 0.2–0.3 mag is clearly seen in the w1-band data of 33 epochs taken in 2010 February and August. The modulation is likely periodic with a period of $\sim 10$–$20 \text{hr}$ (see Figure 1(c) for the modulation, although the phase light curve was folded at 20.87 hr).

4.1. Imaging from the MSU and Lulin Observatories

A monitoring campaign with the 0.6 m telescope in the MSU observatory and the 1 m telescope in the Lulin Observatory was carried out from 2015 October to 2016 January to investigate the $\sim 10$–$20 \text{hr}$ modulation seen in WISE. We observed the source for three consecutive nights from October 10 to 12 with the 0.6 m telescope in the $R$ band (200/300 s for each frame, depending on the weather) and with the 1 m telescope in the SDSS $r$ and $g$ bands for three other nights (i.e., November 8/9 and January 9; only $g$-band images were taken on the first two nights, and both $r$- and $g$-band images were taken by turns on the last night; 60/120 s for the $r$/$g$-band images, respectively).

4.2. Spectroscopy from the Lijiang Observatory

Two 1200 s medium-resolution optical spectra ($5750$–$8800 \AA$) were taken on 2015 November 4 and 5 with the 2.4 m telescope at the Lijiang observatory. After (i) the standard reduction processes with the IRAF package ONEWAVE, (ii) a flux calibration with the standard star BD $+28^\circ$ 4211 (Oke 1990), and (iii) an extinction correction with $A_V = 0.4992 \text{mag}$ (Schlafly & Finkbeiner 2011; which is roughly consistent with the $N_H$ value estimated by Chandra) and the Cardelli extinction law (Cardelli et al. 1989), the calibrated data show spectral shapes comparable to that of a low-mass star (Figure 2) without any accretion features. After matching the data with the synthetic spectra from the Munari online library (Munari et al. 2005; a solar metallicity of $[M/\text{H}] = 0$ and a typical RB rotational broadening of $V = 100 \text{km s}^{-1}$ are assumed), we found that the spectra can be best described by $T = 5750 \text{K}$ and $\log g = 4.5$ (Figure 2), of which the stellar properties are very close to the $M \approx 0.4 \text{M}_\odot$, low-mass companion of the RB PSR J2129–0078 (Bellm et al. 2016). Therefore, we tentatively assume the secondary star of 3FGL J0212.1+5320 to be around $M \sim 0.4 \text{M}_\odot$.

5. DETAILED TIMING ANALYSES

5.1. Orbital Period Determination

After applying the standard data reduction procedures by IRAF on the optical imaging data and removing some bad frames due to bad tracking or bad weather, we used a differential photometric technique to study the optical modulation, which shows a clear sinusoidal shape in all bands (Figure 1(d)). We fitted all the data (including the WISE data; all are heliocentric corrected) simultaneously with sinusoidal functions with common period and phases, but different amplitudes and baselines for each data set. The best-fit period is $10.43479(7) \text{hr}$ (corresponding to the pulsar irradiation case) or $20.8698(2) \text{hr}$ (the ellipsoidal variation case) with the flux minimum epoch at JJD 2457,305,5551(4) (the phase zero of Figure 1 and the following timing analyses). It is worth noting

http://irsa.ipac.caltech.edu/Missions/wise.html
http://archives.pd.astro.it/2500-10500/
that the data used span over 5 yr of time (i.e., from 2010 to 2015), which leads to a very high accuracy of the best-fit period. The best-fit amplitudes of the bands are roughly consistent with each other within a largest offset of 0.02 mag (i.e., \( a_{\text{w1}} = 0.09 \pm 0.02 \) mag, \( a_{\text{e}} = 0.0845 \pm 0.0009 \) mag, \( a_{\text{r}} = 0.0731 \pm 0.0004 \) mag, and \( a_{\text{i}} = 0.092 \pm 0.007 \)). In particular, the simultaneous r- and g-band data taken by Lulin on January 9 do not show any clear color evolving trend during the phase interval of \( \phi_{10} = 0.42-0.66 \) at \( P = 10.43 \) hr (or \( \phi_{20} = 0.21-0.33 \) at \( P = 20.87 \) hr; Figure 1(d)), suggesting that there is likely no strong orbital color variability. This indicates that the pulsar irradiation effect on the companion is very limited and thus the modulation is probably caused by ellipsoidal variation.

5.2. Radial Velocity (RV) Measurement

Following the method described in Bellm et al. (2016), we first removed the telluric lines of the Lijiang spectra by omitting bands of 6860–7000 Å, 7570–7700 Å, 7150–7350 Å, and 8100–8400 Å. Using the RVSAO Package of IRAF, we used the task \texttt{xcsao} to calculate the barycentric-corrected RVs by cross-correlating the spectral data with the \( T = 5750 \) K synthetic spectrum (all the spectra involved are automatically normalized during the cross-correlation process). Both the spectra were found to be redshifted with RVs of \( 136 \pm 19 \) km s\(^{-1}\) (November 4) and \( 31 \pm 17 \) km s\(^{-1}\) (November 5). By applying the 20.87 hr (or 10.43 hr) ephemeris, the orbital phases of the RVs are \( \phi_{20} = 0.34 \) (or \( \phi_{10} = 0.69 \)) and \( \phi_{20} = 0.47 \) (or \( \phi_{10} = 0.95 \)), respectively. For the pulsar irradiation case (i.e., the orbital period is 10.43 hr), the companion should be moving from behind the pulsar to the front in the orbital interval of \( \phi_{10} = 0.5-1 \) (i.e., \( \phi_{20} = 0.25-0.5 \) in Figure 1(a)), during which the lowest RV occurs at \( \phi_{10} = 0.75 \) (i.e., \( \phi_{20} = 0.375 \)). Therefore, the RV at \( \phi_{10} = 0.95 \) (i.e., \( \phi_{20} = 0.47 \)) should be higher than that at \( \phi_{10} = 0.69 \) (i.e., \( \phi_{20} = 0.34 \)). However, the result shows differently, indicating the invalidity of the irradiation case (see Figure 1(a) for a more clear demonstration). On the contrary, the observed RVs can be naturally explained in the case of ellipsoidal variation if the orbital phase zero is defined as the inferior conjunction (i.e., the companion is between the pulsar and the observer; Figure 1(a)).

5.3. Eclipsing Light Curve (ELC) Fitting

We used the ELC code (Version 3; Orosz & Hauschildt 2000) to model the optical light curves (i.e., \( R \) and \( g \) bands) obtained from the MSU and Lulin observatories for a deeper understanding of the interacting binary. For the \( R \)-band data, we omitted the short \( r \)-band light curve (i.e., 2.4 hr) obtained from Lulin to prevent extra systematic uncertainties originating from the cross-calibrations between different filter systems (i.e., \( r \) and \( R \) bands) and instruments. As ELC is capable of fitting RV, we also considered the two RVs to have a better constraint on the fitting result, despite the limited data quantity/quality. We also allowed a tiny phase shift between the phase-folded light curves and the models to further calibrate for the epoch of the inferior conjunction (i.e., the phase zero of the ELC models).

By (i) using the orbital period of \( P_{\text{orb}} = 20.8698 \) hr, (ii) assuming that the effective temperature of the companion is \( T_{\text{eff}} = 5750 \) K (it was not well determined because the ELC fit is insensitive to the companion temperature as ELC fits the normalized light curves) and the mass of the secondary star is \( m_{2} \sim 0.4 \) \( M_{*} \) (by setting \( m_{2} = 0.3-0.5 \) \( M_{*} \)), (iii) disabling the radiation heating effect, (iv) adopting the linear limb-darkening law (van Hamme 1993) with a coefficient of \( \kappa = 0.6483 \) (Sing 2010), and (v) setting a circular orbit (i.e., \( e = 0 \)), we fitted the light curves by varying four binary parameters, which are the binary inclination \( (i) \), the mass ratio \( (q = m_{1}/m_{2}) \), the orbital separation \( (a) \), and the Roche lobe filling factor \( (\beta) \). The ratio of the volume-averaged radii of the companion star and the Roche lobe; Joss & Rappaport 1984). With the built-in optimizer \texttt{gridELC}, we searched for the best-fit solution by minimizing the \( \chi^{2} \) value, and the least reduced chi-square of \( \chi_{r}^{2} = 3.1 \) ( dof = 344) was found at \( i = 90\degree, q = 6.8, a = 4.6R_{\odot} \), and \( \beta = 0.64 \) (\( m_{1} = 1.5M_{\odot} \) and \( m_{2} = 0.2M_{\odot} \) are inferred). It is not a good fit statistically, and the extreme inclination at the upper bound may imply that the fit did not converge.\(^7\) In addition, we found that the data can be fitted fairly well even if a fixed inclination angle of a different value is used (see the similarity between the best-fit models at different inclinations in Figure 1(d)). Therefore, instead of

\(^7\) We once considered turning on the radiation heating effect to improve the fit. However, the flux overestimation in the valley at \( \phi < 0.5 \) is the main cause of the bad fitting. The radiation heating effect will even increase the predicted flux there to worsen the fit.
estimating the parameter uncertainties, we obtain and discuss the best-fit parameter sets at different inclinations from $i = 90^\circ$ to $i = 60^\circ$ with a step size of 5°. To elaborate the choice of $i = 60^\circ$, it was chosen based on the $\chi^2$ values of the RVs on the ELC fits ($\chi^2_{RV}$). Despite the complexity of the optical emission revealed by the bad ELC fit, the RV data in principle would not be affected, making $\chi^2_{RV}$ a useful indicator to test the model validity. In this case, we chose a criterion of $\chi^2_{RV} < 3.84$ (95% c.l. for dof = 1) to reject all other steps of $i < 60^\circ$ with large $\chi^2_{RV}$. We note that the selection heavily depends on the weighting on the RV data in the ELC fit (i.e., no weighting applied here) and therefore the rejection does not imply that the inclination has to be $i > 60^\circ$. The selection simply indicates that the unweighted best-fit models with $i < 60^\circ$ are inconsistent with the RV data, and thus no discussion will be given on those fits.

Figure 3 shows the best-fit Roche lobe filling factors and the inferred pulsar masses for $i = 60^\circ$–90°. As expected, the best-fit filling factor decreases with the inclination (from 0.70 to 0.64). All the best-fit results lead the primary star’s mass to the range of $m_1 = 1.5$–2.2 $M_\odot$ (and $m_2 \approx 0.2 M_\odot$), which is consistent with that of a pulsar. Certainly, the errors of the best-fit pulsar masses could be large (e.g., the uncertain companion mass as one of the major sources of error). Also, we found that the ELC fits are not robust. For instance, if we remove the constraints on the RV curve (i.e., the two Lijiang data points) and the companion mass (i.e., $m_2 = 0.3$–0.5 $M_\odot$), the best-fit solution of $i = 90^\circ$ changes to $q = 7.7$, $a = 5.0 R_\odot$, and $\beta = 0.63$, with which $m_1 = 2.0 M_\odot$ and $m_2 = 0.3 M_\odot$ are inferred (see Figure 3). Even two RV data points and a weak constraint on the companion mass are sufficient to significantly affect the fitting result. Therefore, we conclude that the best-fit parameters and the inferred masses are merely indicative. Detailed modeling (e.g., by adding hot/cool spots on the companion) and high-quality photometry sets and spectroscopic data of a complete orbit are required to place a further constraint on the pulsar mass. More imaging and spectroscopic observations are being planned to probe the system in the near future.

5.4. Possible X-Ray Orbital Modulation

As mentioned in Section 3, there is a significant variability seen in both Swift/XRT and Chandra data, which is possibly induced by the X-ray orbital modulation. We thus folded the light curve with the 20.87 hr timing solution after converting the Chandra X-ray flux into the Swift/XRT band (i.e., 0.3–10 keV) and performing a barycentric correction to the data. Although the folded X-ray light curve does not cover a full orbital cycle, the X-ray variation is likely periodic with an X-ray minimum around the inferior conjunction (Figure 1(b)). A similar phenomenon has been previously seen in the RB PSR J1023+0038 (Bogdanov et al. 2011; Li et al. 2014; Tendulkar et al. 2014). From the Chandra data bins, the X-ray maximum occurs around the superior conjunction (i.e., $\phi_{20} \sim 0.5$; observer-pulsar-companion), although the Swift data favor the flux maximum around $\phi_{20} > 0.5$.

6. DISCUSSION AND CONCLUSION

We presented a multiwavelength study of 3FGL J0212.1+5320 and found that an RB MSP binary as its physical nature can naturally explain the entire data set. The X/$\gamma$-ray spectral properties and the hourly timescale orbital period are very similar to that of many known RBs (Table 1), revealing the first hint of 3FGL J0212.1+5320 as an RB candidate. The inferred primary star’s masses from the best-fit ELC models are 1.5–2.2 $M_\odot$, which are consistent with that of a neutron star, though they are only indicative estimates. An hourly variability is seen in the Swift/Chandra joint light curve, and it could be an orbital modulation, although uncertainly. If the modulation is genuine, it could be caused by an intrabinary shock emission, through Doppler boosting with a pulsar-wrapping shock geometry (Li et al. 2014) or partial occultation by the companion (Bogdanov et al. 2011). All the observational evidence is pointing to the conclusion of 3FGL J0212.1+5320 as a newly discovered RB system.

A bright optical counterpart (could be one of the brightest known for RBs) has been identified with a clear orbital modulation at 20.87 hr. We do not see an obvious nonuniform radiation heating contributing to the orbital modulation, and therefore the companion is probably not completely tidally locked. This may imply that 3FGL J0212.1+5320 is a very young MSP system. According to Zahn (1977), the synchronization timescale of such a close binary is approximately $t_{\text{sync}} \sim 10^{7}(1 + q_i)^{2/3}(P/1 \text{ day})^{4/3} \text{ yr}$ (Equation (6.1) of Zahn 1977), where $q_i$ and $P_i$ are the initial mass ratio and orbital period, respectively. Assuming an initial mass ratio of $q_i = 2.8$ (i.e., $m_{1,i} = 1.4 M_\odot$ and $m_{2,i} = 0.5 M_\odot$), $P_i \approx 13 \text{ days}$ gives $t_{\text{sync}} \gtrsim 10^9 \text{ yr}$ and $P_i \approx 4 \text{ days}$ gives $t_{\text{sync}} \gtrsim 10^7 \text{ yr}$. We took the calculated timescales for 3FGL J0212.1+5320 as lower limits because the orbital widening by the ablation from the pulsar (Chen et al. 2013), which would extend the synchronization process, was not considered in Zahn’s work. In the case of $t_{\text{sync}} \gtrsim 10^7 \text{ yr}$, the initial orbital period is actually close to the estimated value of PSR J2129–4929 (i.e., $P_i \approx 2.5 \text{ days}$; Bellm et al. 2016), which has a long orbital period of $P = 15.2 \text{ hr}$, comparable to 3FGL J0212.1+5320’s. Obviously, a young age of 3FGL J0212.1+5320 (i.e., on the order of 10 Myr) would be a self-consistent explanation for the data. In fact, 10 Myr old MSPs are rare but not impossible. For example, PSR J1823–3021A, one of the youngest MSPs known, has a characteristic age of 25 Myr (Freire et al. 2011). Searching for the radio/X/$\gamma$-ray pulsations of 3FGL J0212.1+5320 and computing the

---

8 The equation presented here is slightly different from the one in Zahn (1977) because of the different definitions of the mass ratios.

9 The initial masses are both poorly known due to the highly uncertain accretion and ablation processes, and thus the values are merely estimated within reasonable ranges.
characteristic age would be useful for investigating the speculation.

Despite no heating effect seen, it is still highly likely that the companion is uniformly irradiated by the $X/\gamma$-rays from the pulsar, resulting in a higher surface temperature than a $\approx 0.4 \, M_\odot$ star should have. As the companion mass is no longer the only dominant factor to determine the surface temperature, the assumption of $m_2 \approx 0.4 \, M_\odot$ (see Section 4.2) could be overestimated. Considering the fact that all the fitting results indicate a lighter $m_2$, $m_2 \lesssim 0.4 \, M_\odot$ would be more reasonable.

As the companion has a temperature close to that of the Sun, it is convenient to use the solar $R$-band absolute magnitude (i.e., $R = 4.42$ mag; Binney & Merrifield 1998) to infer the distance of 3FGL J0212.1+5320. From the ELC model fits, the size of the companion is about $R_c \approx 1 \, R_\odot$. After a proper scaling, the inferred distance is about $d \approx 0.8$ kpc, leading to an $X$-ray luminosity of $L_X \approx 10^{32} \, \text{erg s}^{-1}$, which is relatively high among the known X-ray RBs in the pulsar state (when radio pulsations can be detected and $L_X \sim 10^{33} - 4 \times 10^{32} \, \text{erg s}^{-1}$; Linares 2014). Since a high X-ray luminosity (i.e., $L_X \approx 10^{32} \, \text{erg s}^{-1}$) in the pulsar state is a common feature of all three known tMSPs (i.e., PSR J1023+0038, PSR J1227−4853, and M281), it has been suggested by Linares (2014) that $L_X \gtrsim 10^{32}$ is possibly a consequence of a stronger interaction between the pulsar and the companion, and therefore the higher X-ray luminosity could be a signature of an RB binary developing a strong accretion for the transition. One possibility is that the companion of a pre-transition (to the LMXB state) system has a stronger wind (i.e., a stronger inflow to the pulsar; see Takata et al. 2014; Li et al. 2014, for the interpretation of a varying stellar wind as the transition trigger for PSR J1023+0038), which powers a stronger intrabinary shock X-ray emission. Based on the X-ray luminosity, two bright systems, PSR J2215+5135 ($L_X = 1.3 \times 10^{32} \, \text{erg s}^{-1}$) and PSR J1723-2837 ($L_X = 2.4 \times 10^{32} \, \text{erg s}^{-1}$; see Table 1 for their $\gamma$-X-ray properties), have been suggested by Linares (2014) to be potential targets for state transitions in the near future. 3FGL J0212.1+5320 could be the third member of the group. In addition, we also examined the X-ray-to-$\gamma$-ray flux ratios of some known RBs and found that the flux ratios of the tMSPs (i.e., $\gg 1\%$) are significantly larger than that of the "normal" RBs (i.e., $\lesssim 1\%$). 3FGL J0212.1+5320 has a ratio of 7.9% that is consistent with the tMSP ones. One of the two prospective tMSP candidates, PSR J1723−2837, also has a large ratio of 13% (Table 1).

Certainly, the speculation is not mature and should not be taken conclusively. However, it is still worth paying attention to the X-ray activity of 3FGL J0212.1+5320 for any future transition. Even if it is not exhibiting any transition in the near future, 3FGL J0212.1+5320 could be one of the brightest RBs in X-rays and certainly is one of the best sources for studying the X-ray emissions of RBs.

No previous attempt of a radio pulsation blind search for 3FGL J0212.1+5320 has been found in the literature (Ransom et al. 2011; Guillemot et al. 2012; Camilo et al. 2015). In fact, the system is likely radio-faint as no radio counterpart can be found in the 1.4 GHz NRAO/VLRA Sky Survey, of which the detection limit is $\approx 2.5 \, \text{mJy}$ (Condon et al. 1998; note that most of the radio MSPs found by targeting Fermi-LAT sources have flux densities much lower than 2.5 mJy at 1.4 GHz; Ray et al. 2012). Nevertheless, a GBT observation is being planned for searching for radio coherent pulsations. Hopefully, this extreme RB MSP (i.e., high X-ray luminosity, bright optical companion, long orbital period, and potentially young age) can be confirmed soon.

After the submission of this paper, we became aware of a similar work by Linares et al. (2016), in which results including the measured orbital period, the RV curve of the companion, the Chandra spectral analysis, and the RB MSP nature interpretation are consistent with ours. In particular, they have sampled a much better RV curve, which would be very helpful in searching the radio/$\gamma$-ray pulsations in the future.
