Arraymetrics: Authentication Through Chaotic Antenna Array Geometries
Murat Karabacak, Berker Peköz, Gökhan Mumcu, Member, IEEE and Hüseyin Arslan, Fellow, IEEE

Abstract—Advances in computing have resulted in an emerging need for multi-factor authentication using an amalgamation of cryptographic and physical keys. This letter presents a novel authentication approach using a combination of signal and antenna activation sequences, and most importantly, perturbed antenna array geometries. Possible degrees of freedom in perturbing antenna array geometries affected physical properties and their detection are presented. Channel estimation for the plurality of validly authorized arrays is discussed. Accuracy is investigated as a function of signal-to-noise ratio (SNR) and number of authorized arrays. It is observed that the proposed authentication scheme can provide 1% false authentication rate at 10 dB SNR, while it is achieving less than 1% missed authentication rates.

Index Terms—antenna arrays, authentication, chaotic communication, communication system security, MIMO communication.

I. INTRODUCTION

T he emergence of quantum computing has recently shown that currently used conventional encryption techniques can be cracked with ease in the near future [1]. This pushed researchers to finding new horizons that satisfy security requirements through the use of non-cryptographic approaches [2], such as utilizing the physical layer (PHY) properties of the system [3] or machine learning (ML) techniques [4] to infer presence of adversaries and defend accordingly. Quantum password cracking aside, PHY authentication becomes critical in authenticating simplex broadcasts in which cryptographic approaches cannot be utilized, such as spoofed global positioning system (GPS) signals as in [5]. In [6], layered security approaches were investigated in detail, and were shown to be redundant and inflexible for future network structures [7].

Authenticating user equipments (UEs) using their PHY characteristics in developing a PHY security (PLS) approach have been gaining traction [8]. The idea of extracting artifacts caused by imperfections in the source network interface card (NIC) to authenticate devices have been around for more than a decade [9]. Channel similarities in addition to the RF fingerprint of the device, of which recent extraction advances is detailed in [10], are also utilized in the control-layer based authenticator designed in [11], that aims to replace high-latency connections to remotely located authentication servers with local verification among fifth generation (5G) heterogeneous network (HetNet) access points (APs).

Antenna array geometry optimization literature has historically focused on designing "smart" [12] or adaptive antenna arrays with improved far- or near-field spatiotemporal localization [13]; and is rich in this context. Although PLS using multiple antennas was also introduced more than a decade ago when signals received from multiple-input multiple-output (MIMO) transmitters are authenticated using the spatiotemporal correlation of the wireless channel in [14]. However, due to the randomness of the channel this method can provide limited control on spatiotemporal signatures. Despite the further studies of PHY security of MIMO systems in [15], [16], the literature for PHY authentication for this systems remains underdeveloped to date.

Physical layer security aspect of multiple antenna configurations were most recently evaluated to the extent of passive confidentiality and active availability attacks using massive MIMO (MaMIMO) systems [17]. Recent developments in signals intelligence (SIGINT) techniques for MIMO wireless communications are surveyed in [18]. A secure receive spatial modulation scheme that randomizes precoders but not antenna arrays is proposed in [19].

In this work, we propose a novel authentication scheme that combines chaotic antenna array geometries with pseudorandom pilot sequences and antenna array activation sequences. This novel approach combining all three allows unclonable authentication devices, even if the adversaries eavesdrop the message exchange or figure out the unique antenna array geometry by x-ray radiography. The accuracy and scalability of the approach is investigated. It is observed that the proposed authentication scheme can provide 1% false authentication rate at 10 dB SNR, while it is achieving less than 1% missed authentication rates.

The rest of this paper is organized as follows: Section II provides the adopted system model. Section III introduces the proposed chaotic and pseudorandom designs and briefly presents their effects on the detection metrics. The detection performance results are shown in Section IV. Finally, the paper is concluded in Section V.

Notation: Throughout this paper, vectors are represented using lowercase bold-face letters, matrices are uppercase bold-face letters, and non-bold letters are used for scalars. The superscripts \( (\cdot)^\mathbb{H} \) stands for the conjugate-transpose operation. \( \mathbb{C}, \mathbb{Z} \) and \( \mathbb{R} \) represent the complex, integer and real number domains, respectively. \( \sim \mathcal{CN} (\mu, \sigma^2) \) corresponds to complex Gaussian distributed random variable with mean \( \mu \) and variance \( \sigma^2 \), and \( \mathcal{U} (a, b) \) corresponds to the uniformly distributed
random variable between $a$ and $b$. $||\cdot||$ corresponds to the Euclidean norm, $A \otimes B$ and $A \odot B$ correspond to the Hadamard multiplication of matrices $A$ and $B$ and division of matrix $A$ to $B$, respectively.

The authenticating device and the device being authenticated will hereinafter be referred to as “Seraph” and “Neo”, respectively, with subscripts $_x$ and $_n$ used to describe their respective attributes.

II. SYSTEM MODEL

The working principle of this system is similar to that of an active radio frequency (RF) identification (RFID) tag. However, instead of the device-specific variation of binary load state or load impedance as a function of time, it is assumed that upon their first encounter which takes place in a controlled environment, Seraph characterizes and saves the following identifying information about Neo in an allowlist:

- The chaotic antenna array geometry equipped by Neo, as exemplified in [Fig. 1]
- The particular antenna activation sequence used by Neo,
- The particular pilot sequence transmitted by Neo.

This section contains technical definitions for these information sources. This section and subsequent sections investigate ensuing encounters, during which Seraph authenticates Neo’s identity by simultaneously verifying all abovementioned attributes of Neo real-time in uncontrolled environments. The analysis further assumes that, as is the case with RFID tags, Seraph and Neo are synchronized; and the wireless propagation channel between each antenna of Seraph and Neo is representable in the form of a single tap over the utilized bandwidth without loss of generality, is also time-invariant throughout the transmission interval, and is known by Seraph through readily available techniques.

Neo is equipped with $M_n = H_n \times V_n \in \mathbb{N}$ antennae wherein $H_n \in \mathbb{N}$ and $V_n \in \mathbb{N}$ correspond to the number of antennae on the horizontal and vertical edges of Neo’s 2D antenna array. Neo’s 2D antenna array starts off as a standard $\lambda_0/2$ spaced uniform linear antenna array (ULA), where $\lambda_0$ is the free space wavelength at the center carrier frequency. Each antenna element starts off as square patch of edge length $\lambda_k/2$, where $\lambda_k < \lambda_0$ is the guided wavelength at the center carrier frequency, and each antenna element is translated, rotated, scaled or skewed chaotically from its original location, respectively, and $\hat{i}$ and $\hat{j}$ are the horizontal and vertical unit length vectors, respectively. Furthermore, the joint probability density function (PDF) for any two displacement satisfies $f_{\Omega, \tilde{\Omega}}(u_{\Omega, \tilde{\Omega}}) \equiv f_{\Omega}(u_\Omega) f_{\tilde{\Omega}}(u_{\tilde{\Omega}})$, and denote the horizontal and vertical displacement of the aforementioned vertex from its original location, respectively, and $\Omega$ and $\tilde{\Omega}$ are independent Gaussian random variables, and $\nu_{0,1} \in \{x, y\}$; $m_{0,1} \in \mathbb{Z}_0^+ \times \mathbb{Z}_0^+$.

Note that by independently displacing all vertices in two dimensions, each antenna element is translated, rotated, scaled or skewed chaotically from the ULAA design as illustrated in [Fig. 1]. As a result, it is assumed that complex noise is introduced to Neo’s spatial signature in the transmit direction of $\Omega$ as $\tilde{\Omega}$

$$h_n(\Omega) = h(\Omega) + \sigma_n \tilde{h} \odot e_n(\Omega),$$

wherein $h(\Omega) \in \mathbb{C}^{M_n \times 1}$ is the spatial signature of Neo’s nonmodified ULAA in the transmit direction of $\Omega$ as described in [20] Eq. (7.24) of which construction is not recited here due to space constraints, $\sigma_n \in \mathbb{R}^+$ is the standard deviation thereof and corresponds to the positive square root of the channel gain, $e_n(\Omega) \in \mathbb{C}^{M_n \times 1}$ is Neo’s nonmodified ULAA unit spatial signature in the transmit direction of $\Omega$ as described in [20] Eq. (7.25), and $\tilde{h} \in \mathbb{C}^{M_n \times 1}$ is the introduced chaotic noise of which each element is $\sim \mathcal{CN}(0, 1)$ independent from others. Accordingly, we will refer to Neo’s final ULAA’s unit spatial signature in the transmit direction of $\Omega$ as $e_n(\Omega) = \frac{\sqrt{\sigma_n} h_n(\Omega) - h(\Omega)}{\sigma_n} \odot \tilde{h}.$

Each antenna is connected to an independent RF chain that is capable of carrying a complex (IQ modulated) sinusoid pulse uncorrelated to those of other antennae. The reciprocal of the duration of each pulse is analogous to widely known “baud rate” and is assumed constant, at least for Neo, to ease practical aspects concerning transceiver implementation. Neo may also utilize nonsinusoidal wavelets, or, further utilize plurality of wavelets wherein each signal element utilizes a different wavelet for further scalability and security, but these are beyond the scope of this art and will be considered in future works to maintain the work in hand concise. Neo transmits the pilot sequence over $T_n \in \mathbb{N}$ baud intervals, and the pilot symbol modulating the sinusoid transmitted from the $m \in \mathbb{Z}_0^+$th antenna during the $t \in \mathbb{Z}_0^+$th baud interval is given in the $m$th row and $t$th column of the pilot matrix $X_n \in \mathbb{C}^{M_n \times T_n}$ and
denoted by \( X_n (m, t) \), wherein \( X_n (m, t) \sim \mathcal{U} (-\pi, \pi) \) and
\[
|X_n (m, t)| = \begin{cases} \sim \sqrt{\mathcal{U} (0, 1)}, & \nu_{n,m,t} \geq \nu_n, \\ 0, & \text{otherwise}, \end{cases}
\] (3)

where \( \nu_{n,m,t} \sim \mathcal{U} (0, 1) \) is a random variable that determines whether Neo’s \( m \)th antenna during the \( t \)th baud interval and \( \nu_n \) is Neo’s activation threshold that determines the antenna activation probability; furthermore \( f_p (\nu_{n,m_0, t_0}, \nu_{n,m_1, t_1}) = f_p (\nu_{n,m_0, t_0}) f_p (\nu_{n,m_1, t_1}) \forall m_0, m_1 \in \mathbb{Z}, t_0, t_1 \in \mathbb{Z} \). A zero entry in \( X_n \) implies that no transmission occurs from that antenna during that baud interval. Therefore, \( X_n \) describes the particular antenna activation sequence used by Neo in its columns, and the particular pilot sequence transmitted by Neo in its elements.

Seraph is equipped with \( N_s \in \mathbb{N} \) antennae that is formed in a nonmodified 2D ULAA, and has the default spatial signature thereof. Accordingly, the channel matrix \( H_n \in \mathbb{C}^{N_s \times M_n} \) is composed as done in [20, Eq. (7.56)], with the difference being the unit spatial signature in the transmit direction of \( \Omega \) term denoted by \( e_1 (\Omega) \) is replaced with \( e_n (\Omega) \) derived in (2). The signal received at Seraph’s \( n < N_s \)th antenna at the end of the \( t < T_n \)th baud interval is on the \( n \)th row and \( t \)th column of \( y_s \in \mathbb{C}^{N_s \times T_n} \), where
\[
y_s = H_n X_n + w,
\] (4)

where \( w \in \mathbb{C}^{N_s \times T_n} \) is the additive white Gaussian noise (AWGN) matrix comprising independent elements identically distributed with \( \sim \mathcal{CN} (0, (\sigma_r / \gamma_n)^2) \) wherein \( \gamma_n \) is Neo’s SNR.

III. PROPOSED RECEIVER

Since Seraph relies on random deviations of spatial signature, a detection algorithm for Neo’s spatial signature deviation can be implemented to decide if the received signal is coming from Neo or not. The detection algorithm can be derived by correlating Neo’s expected received signal over \( y_s \). The correlation is calculated using
\[
\rho = \text{tr} \left( X_n^H H_n^H y_s \right).
\] (5)

Noise or signal emitted by intruders may also cause high correlation and can cause false positives if solely this measurement is considered. To distinguish Neo’s signal both from noise and signals emitted by intruders, its strength must be compared to that of noise. The noise variance, \( \sigma_n^2 \in \mathbb{R} \), is estimated by similarly correlating \( y_s \) with any signature orthogonal to that of Neo and all other possible authorized users. The detection metric \( \beta \in \mathbb{R} \) is then given by
\[
\beta = \frac{\rho}{\sigma_n^2}.
\] (6)

The detection metric is then compared to a threshold value \( (\beta) \). To minimize the error, one threshold can be selected as half of the distance between two states as
\[
\psi_e = \frac{\text{tr} \left( X_n^H H_n^H H_n X_n \right)}{2 \sigma_n^2}.
\] (7)

IV. PERFORMANCE ANALYSIS

To evaluate the proposed authentication method, link level simulations have been performed under highly scattering Rayleigh channel. Seraph is assumed to have 512 antennas at all times, while Neo may have different number of active antennas depending on \( \eta_n \).

In Fig. 2 missed detection rate of Neo’s signature is presented against SNR. The proposed method fails to authenticate Neo with less than 1% probability at most at 13 dB SNR if \( M_n = 16 \) antennas are activated while \( \text{Pr} (\text{FA}) = 0.001 \). It is also seen that 1% misdetection probability can be achieved when 8 dB SNR for both \( M_n = 16 \) and \( M_n = 128 \) active antennas with relaxed FA requirement of \( \text{Pr} (\text{FA}) = 0.01 \). Lower rates are possible as the number of active antennas are increased or FA probability requirement is relaxed.

Fig. 3 shows FA rates of Neo’s signature when Seraph is only receiving noise. As it is seen from the figure, the desired FA rates of \( \text{Pr} (\text{FA}) = 0.001 \) and \( \text{Pr} (\text{FA}) = 0.01 \) are closely achieved for SNR values up to 12 dB and 10 dB, respectively. After that, SNR values the secondary threshold of \( \psi_e \) becomes effective and improves the FA performance for Neo’s signature detection algorithm. The authors note that, due to the designed threshold calculation based on the desired false detection rate, both results are expected to be as close as
possible to $10^{-2}$ or $10^{-3}$ depending on the threshold. Since higher number of antennas provide better diversity against fading and noise, increasing the number of antennas provides more consistent behaviour that yield results closer to expected. Lower number of antennas may result in reduced false alarm rates due to the way the detector is structured, but increasing number of antennas results in more consistent overall detection rates due to the way the detector is structured, but increasing number of antennas may result in reduced false alarm rates above It is observed that the proposed authentication scheme can provide 1% false authentication rate at 8 dB SNR. Practical approached to randomized chaotic antenna array manufacturing and statistical signature distribution of the manufactured arrays can be investigated as a future study.

**V. CONCLUDING REMARKS**

A novel authentication approach combining chaotic antenna array geometries with signal and antenna activation sequences has been presented. Possible degrees of freedom in perturbing antenna array geometries, affected physical properties and their detection are presented. While enforcing false alarm rate to be less than 1%, the proposed authentication method is able to provide less than 1% missed detection rates above It is observed that the proposed authentication scheme can provide 1% false authentication rate at 8 dB SNR. Practical approaches to randomized chaotic antenna array manufacturing and statistical signature distribution of the manufactured arrays can be investigated as a future study.
