A global equation of state of two-dimensional hard sphere systems

Stefan Luding
Institute for Computer Applications 1, Pfaffenwaldring 27, 70569 Stuttgart, Germany

Hard sphere systems in two dimensions are examined for arbitrary density. Simulation results are compared to theoretical predictions for both the low and the high density limit, where the system is either disordered or ordered, respectively. The pressure in the system increases with the density, except for an intermediate range of volume fractions $0.65 < \nu < 0.75$, where a disorder-order phase transition occurs. The proposed global equation of state (which describes the pressure for all densities) is applied to the situation of an extremely dense hard sphere gas in a gravitational field and shows reasonable agreement with both experimental and numerical data.

A hard sphere (HS) system is a simple and tractable model for various physical phenomena. It was used to examine disorder-order transitions, the glass transition, or simple gases and liquids both theoretically and numerically. The theory that describes the behavior of rather dilute hard sphere systems is the kinetic theory, where particles are assumed to be rigid and collisions take place in zero time. An extension to Boltzmann's low density theory was introduced by Enskog, taking into account excluded volume effects and also momentum transport via collisions. In the limit of high densities, the cage-effect, where particles are captured by their neighbors, becomes important and a free-volume theory can be formulated and references therein.

When dissipation is added to the HS model, one has the simplest version of a granular gas, i.e., the inelastic hard sphere (IHS) model. Granular media represent the more general class of dissipative, non-equilibrium, multiparticle systems. Attempts to describe granular media by means of the kinetic theory are usually restricted to certain limits like small densities or weak dissipation. Also in the case of granular media, one has to apply higher order corrections to successfully describe the system under more general conditions or for multi-particle contacts. The result of a kinetic theory approach is, in the simplest case, a set of balance equations for mass, momentum, and energy with constitutive expressions for the transport coefficients, describing stress, viscosity, heat conduction, and energy dissipation. In this letter, we focus on the pressure $p$, the isotropic part of the stress in a hard sphere gas – or in a granular gas in its elastic limit $r \rightarrow 1$, with the coefficient of restitution $r$. The model system is periodic and two-dimensional (2D) with volume $V = l_x l_y$, where $l_x$ and $l_y$ are horizontal and vertical size, respectively. It contains $N$ particles with radii $a$, and masses $m$ which are located at positions $r_i$ with velocities $v_i$. The fraction of the area which is covered by particles is denoted as volume fraction $\nu = N\pi a^2/V$. The kinetic energy is $E = \frac{m}{2} \sum_{i=1}^{N} v_i^2$, the temperature is defined as $T = E/N$ in 2D and the energy density is $E/V$. For low and intermediate densities $\nu < \nu_c$ (with the “crystallisation” density $\nu_c$ at which order becomes important), the kinetic theory leads to an expression for the equation of state, i.e., the dimensionless excess pressure due to particle interactions

$$P := pV/E - 1 = 2\nu g(\nu).$$

(1)

For an ideal gas with non-interacting particles, one has $pV/E = 1$ so that $P = 0$: for non-zero densities one has $P > 0$ since the collisions contribute to the momentum transport and thus to the pressure, the viscosity, the heat-conductivity and the dissipation rate. In cases with $r < 1$ the factor 2 can be replaced by $1 + r$. The pair correlation function at contact $g(\nu)$ accounts for the probability that a collision occurs. Typically, $g(\nu)$ is determined via a virial expansion around low densities and one can use

$$g_4(\nu) = \frac{1 - 7\nu/16}{(1-\nu)^2} - \frac{\nu^3/16}{8(1-\nu)^4},$$

(2)

where the subscript 4 indicates that the second term is of order $1/(1-\nu)^4$. The first term in Eq. (2) is the simpler, frequently used version $g_2(\nu)$ introduced by Henderson. Note that the expression in Eq. (2) is slightly different from the form in Refs. (4, 2). The value of $g_4$, taken at contact, accounts for the excluded volume effect and the increase of the collision rate with density. At densities larger than $\nu_c \approx 0.7$, an ordered triangular structure is evidenced.

One of the unsolved problems concerning an application of the balance equations to a specific boundary value problem is the limited range of validity of Eq. (3). Under realistic conditions with $r < 1$, the volume fraction can take values $\nu > \nu_c$ so that a solution based on Eqs. (1) and (3) can be correct up to $\nu_c$ only. This is
even worse, since the “virial” \(\nu g(\nu)\) also occurs in all the other transport coefficients. For the same reason, fortunately, a generalization of the pressure \(P\) to all densities will thus enter all the other transport coefficients. This is why we examine the equation of state at all densities and propose a global equation of state which is then tested by a comparison with simulation and experiment.

For the numerical modeling of the system an event driven (ED) method \cite{23,24} is used. A change in velocity can occur only at a collision when the standard interaction model, based on momentum and energy conservation is used \cite{12}. The post-collisional velocities \(v'\) of two collision partners, in their center of mass reference frame, are given in terms of the pre-collisional velocities \(v\), by \(v'_{1,2} = v_{1,2} \mp (\langle v_1 - v_2 \rangle \cdot \hat{n}) \hat{n}\), with the unit vector \(\hat{n}\), pointing along the line connecting the centers of the colliding particles. This model can also be extended to the more general case of dissipative particles with rough surfaces \cite{12,13}.

The stress tensor inside a test-volume \(V\) (whose isotropic part is the pressure \(p\)) has two contributions, one from the convectional transport of mass and thus momentum and the other due to collisions and the related momentum transport, for details see Refs. \cite{23,24,25} and references therein. The mean pressure is obtained from simulations with different volume fractions \(\nu\) in the following.

The equation of state in the dense, ordered phase has been calculated by means of a free volume theory \cite{23,24,27} that leads in 2D to the reduced pressure \(P_{\nu c} = c_0/(\nu_{\text{max}} - \nu) - 1\), with \(c_0 \approx 1.8137\) as obtained from our numerical data. Based on the simulation results we propose the corrected high density pressure

\[
P_{\text{dense}} = \frac{c_0}{\nu_{\text{max}} - \nu} h_3(\nu_{\text{max}} - \nu) - 1\tag{3}
\]

where \(h_3(x)\) is a fit-polynomial \([1 + c_1x + c_3x^3]\) of order three, with \(c_1 = -0.04\) and \(c_3 = 3.25\) \cite{29}.

What remains to be done is to merge the low density pressure \(P_4\) and the high density expression \(3\). To our knowledge, no theory exists, which connects these two limiting regimes. For various approaches concerning the melting and freezing transition see Refs. \cite{8,22,27,29}. Therefore, we propose the global equation of state

\[
Q = P_4 + m(\nu)[P_{\text{dense}} - P_4],\tag{4}
\]

with an empirical merging function

\[
m(\nu) = \frac{1}{1 + \exp \left[ - (\nu - \nu_c)/m_0 \right]}\tag{5}
\]

which selects \(P_4\) for \(\nu \ll \nu_c\) and \(P_{\text{dense}}\) for \(\nu \gg \nu_c\), with the width of the transition \(m_0\). The parameters \(\nu_c = 0.7006\) and \(m_0 = 0.0111\) lead to qualitative agreement between \(Q\) and the simulation results – by far better than 1 per-cent for the purely ordered and disordered regimes, and still within about 3 per-cent in the interval \(0.65 \leq \nu \leq 0.75\) \cite{31}.

![Figure 1](image-url)

**FIG. 1.** Global, dimensionless equation of state \(Q\), plotted against the volume fraction \(\nu\) with logarithmic vertical axis. The dashed and dotted lines correspond to \(P_4\) and \(P_{\text{dense}}\), respectively, see Eqs. (1), (2), and (3). In the inset, simulation data \(N = 1628, r = 1\) are compared with \(Q\).

When plotting \(P\) against the volume fraction \(\nu\) with a logarithmic vertical axis in Fig. 1 the results for the different simulations can not be distinguished from the theoretical prediction \(P_4\) for \(\nu \sim 0.65\). For larger volume fractions one obtains crystallisation around \(\nu_c \approx 0.70\) and the data clearly deviate from \(P_4\). In the transition regime, the coexistence of fluid and solid phases can be obtained. The pressure is strongly reduced due to the enhanced free volume in the ordered phase. The reduced pressure data eventually diverge at the maximum packing fraction in 2D \(\nu_{\text{mono}}^\text{dense} = \pi/(2\sqrt{3})\). Note that one has to choose the system size such that a triangular lattice fits perfectly in the system, i.e. \(h/l_x = \sqrt{3}h/2w\) with integer \(w\) and even \(h\) – otherwise the maximum possible volume fraction can be smaller. Since our simulations are already set up on a perfect triangular lattice, the maximum density is approached for \(\nu \to \nu_{\text{max}}\). If, instead, the volume fraction is increased by increasing the particle size \cite{24,26} and the simulations are started from random, low density configurations, \(\nu_{\text{max}}\) is not reached due to defects in the 2D crystal \cite{27,28}. Thus our global equation of state represents the high density, small compression-rate limit.

The transition by itself is also interesting, since we obtain a hysteresis loop when the density is increased and decreased with a finite rate \cite{23,25,26}. Especially in the transition region, the relaxation time is very large, and the inflection in the data (see the inset in Fig. 1) can be due to either the finite relaxation time, the finiteness of the system or the initial and boundary conditions \cite{30,31}. Note that the analytical expression \(Q\) allows for a straightforward numerical integration of the den-
sity profile (see below), since the fit-parameters are chosen such that the slope of $Q$ is always positive. This is a compromise between the quality of the fit on the one hand and the numerical treatability of the function on the other hand – instabilities are avoided but also memory effects are disregarded.

For a HS system in a gravitational field with the acceleration $g$ in the negative vertical direction, both density- and pressure gradient have to be taken into account. In the following, we compute analytically the density profile for an ideal gas ($\nu < 0.65$): the profile for the extremely dense gas is computed numerically using the global equation of state and is found to be in excellent agreement with the numerical ED simulations, where a compromise between the quality of the fit on the one hand and the numerical treatability of the function on the other hand – instabilities are avoided but also memory effects are disregarded.

In the simplest case, the equation of state of an ideal di-

erary effects are disregarded. In Fig. 2, the volume fraction

$\nu < \nu^*$ instead of $2\nu^g$ is used to express the

derivative $\nu$ with the unknown volume fraction $\nu_0$ at $z_0$, again determined the integral over the density. This leads to a third order polynomial for $\nu_0$, which can be solved analytically \[3\], and has at least one real solution. When the theoretical density profile in Eq. \[6\] is compared with numerical simulations, one obtains perfect agreement for $\nu < 0.65$ \[3\]. Since the functions $g_2(\nu)$ and $g_4(\nu)$ are wrong at larger densities $\nu$, one cannot expect that the pressure and the density profile are correct.

Using the global equation of state, $Q$, from Eq. \[1\] instead of $2\nu g_2(\nu)$, one has to integrate the differential equation $dp/dz = -nmg$ numerically with $p = nT(1+Q)$ under the constraint that the particle number is a constant. In Fig. 2, the volume fraction $\nu$ is plotted against the rescaled height $z/z_T$ for both theory and simulations. Simulation parameters are $N = 1000$, $L = 10$, and $z_T/(2a) = 5.85$ (open circles) or $N = 3000$, $L = 50$, and $z_T/(2a) = 0.508$ (open squares). In addition, we present experimental results from vibrated two-dimensional arrays of small spheres \[14\] (solid dots), neglecting the fact that this situation is weakly dissipative. Both the qualitative and the quantitative behavior of the density profile is well reproduced by the numerical solution using the global equation of state. All solutions belong to one master curve and can be rescaled by a horizontal shift. The averaging result is somewhat dependent on the averaging procedure – we evidence strong coarse-graining effects in the dense, ordered regime with densities $\nu > 0.70$. Using two methods, one tailored for the ordered regime and the other for the disordered regime, however, we obtain consistent results.

\[\text{FIG. 2. Volume fraction of the hard sphere gas as a function of the rescaled height } z/z_T \text{ for different } \nu_0 \text{ values as given in the inset. Lines are the theoretical predictions with increasing bottom density, from left to right, open symbols are two simulations and the solid dots are the experimental data from Ref. \[3\].}\]

In summary, we tested existing predictions for the equation of state of a 2D hard sphere gas of arbitrary density via comparison with numerical simulations and experimental data. In the dilute case, the particle correlation at contact and the collision frequency (and thus the equation of state) are nicely predicted by the kinetic theory expressions up to intermediate densities $\nu \approx 0.65$. In the dense case, the free volume theory for 2D systems can be applied to systems with densities larger than $\nu \approx 0.75$. Finally, a merging function is proposed, which connects the low and high density regimes, resulting in a differentiable \textit{global equation of state} for the 2D hard sphere gas for arbitrary density.

The equation of state is used to compute analytically and numerically the density profile of an elastic, monodisperse HS gas in a gravitational field. For maximum densities below $\nu_c$, the analytical solution works perfectly
well, for higher densities, we used a numerical solver (MAPLE). The strange shape of the density profile as obtained from simulations is nicely reproduced by our theory based on the global equation of state, including a wiggle at \( \nu \approx \nu_c \). We remark that the ED simulation method parallels the Monte Carlo (MC) method concerning the particle-particle interactions, but in contrast to MC allows for a definition of time and thus for the examination of the dynamics.

The presented results are obtained from homogeneous, elastic systems of arbitrary density. The range of applicability, however, is much wider. Since already weak dissipation can lead to strong inhomogeneities in density, temperature, and pressure, the global equation of state is a necessary tool to treat effects like clustering, surface-waves, pattern formation, or phase-transition and coexistence by means of a continuum theory. In a freely cooling “granular gas”, for example, clustering leads to all densities between \( \nu \approx 0 \) and \( \nu \approx \nu_{\text{max}} \).

The proposed global equation of state is based on a limited amount of data from ED simulations. First checks, whether our global equation of state still makes sense for different particle-size distribution functions are promised, however, the crystallisation effect vanishes for strong enough polydispersity. What remains to be done is to find similar global expressions for other transport coefficients like the viscosity and the heat-conductivity and, furthermore, to extend the presented approach to three dimensional systems.
