Numerical study of a wide-angle near-perfect absorber for the visible regime incorporating metal-dielectric-metal subwavelength grating structure

Wenlong Zou1,2 · Heng Zhang1,2 · Yun Zhou1,2

Abstract A near-perfect absorber for the visible regime based on metal-dielectric-metal subwavelength grating structure with the refractory metals is designed and demonstrated numerically. The absorber presents an average absorption over 98.4% in the visible regime at normal incidence. Angle-relative analysis shows that the proposed structure has good angle-tolerance. The high average absorption (86.6%) in the visible region can be maintained with the incident angles up to 60°. Through the analysis of the magnetic field, the physical origin is verified that this excellent absorption performance mainly stems from the cooperative effect of surface plasmonic resonances and the intrinsic broadband spectral responses by the refractory metals. In addition, the dependence of the absorption spectrum of the proposed absorber on the structural parameters is analyzed. This work provides an idea for the design of high-performance absorbers and has potential applications in advanced light energy capture and integration systems.

Keywords Optical devices · Metamaterial absorber · Visible · Absorption

Introduction

Since Landy et al. first demonstrated a perfect metamaterial absorber (MA) at 11.5 GHz, MAs have attracted great interest because of their wide applications, such as solar cells, plasmonic sensors, photodetectors, and thermal emitters [1–23]. Adjustable-band, omnidirectional, and polarization-independent absorbers based on the metamaterial or meta-surface have been investigated. Under appropriate conditions, the absorption can be enhanced by intrinsic electron resonance and magnetic resonance, including surface plasmon resonance (SPR), cavity mode resonance (CMR), Mie resonance (MR) or hybrid resonance [5–10]. In the previous studies, a lot of research work focuses on infrared band, or longer band absorption [4, 5]. In recent years, with the rapid development of micro-nano-processing technology, people gradually pay attention to the absorber working in the visible regime [7, 9, 10, 17, 20, 24–28]. For example, Qinyu Qian proposed and experimentally demonstrated an ultrathin meta-surface perfect absorber based on coupled Mie resonances with dielectric Si nanopillars and metallic Cr nanopillars [10]. Sunwo Han et al. numerically investigated and analyzed the electromagnetic resonances on a 2D tandem grating and its application for broadband absorption in the visible spectrum [24]. Minghui Luo et al. proposed a broadband absorber based on a metallic substrate and a 1D subwavelength metallic grating with the grooves filled with dielectric material in the visible regime [17]. Recent literature shows that the combination of meta-surface and the refractory material can achieve efficient broadband absorption in the visible band. Yuyin Li proposed an ultra-broadband perfect absorber composed of the insulator–metal–insulator–metal (MIM) film stacks utilizing refractory materials, achieving over 90% absorption in the wavelength range from 570 to
3539 nm with an average absorption of 97% [20]. These structures mentioned above are very sensitive to structural parameters, so there are strict requirements for machining means, which limit practical device applications. Although some progress has been made, further research on broadband absorbers using refractory materials is needed.

In this paper, a wide-angle near-perfect absorber incorporating metal-dielectric-metal subwavelength grating with refractory materials is presented. An average absorption of 98.4% for the whole visible regime at normal incidence is attained. Particularly, near-perfect absorption (about 99.6%) is achieved at \( \lambda = 600 \) nm. Moreover, the high average absorption (86.6%) can be maintained in the visible region with the incident angle varying from 0 to 60°. The high broadband absorption is attributed to the cooperative effect of surface plasmonic resonances supported by the multilayered structure and the intrinsic broadband spectral responses by the refractory metals. Additionally, the absorption spectra of different structure parameters are studied. The near-perfect absorber presented in this paper has potential application prospects in color-printing, solar-energy harvesting, and other fields.

Simulation and discussion

Figure 1 shows the schematic diagram of the proposed absorber, consisting of the bottom metal layer of the refractory material tungsten (W), the dielectric layer (SiO\(_2\)), and the subwavelength metal (W) grating layer. The heights of them are \( h_1, h_2, \) and \( d \), respectively. The metal grating in this structure is also characterized by the period \( p \), the ridge width \( a \), and the duty cycle \( F \) \( (F = a/p) \). The refractive index of W is fitted by the Drude-Lorentz model [29]. The refractive index of the dielectric layer is 1.5. In the structure, the bottom W layer with the thickness larger than the skin depth is employed to hinder the transmission. The subwavelength metal grating arrays are symmetric along the \( X \) and \( Y \) directions, indicating that the desirable polarization-independence could be deservedly obtained. In order to simplify, the TM-polarized light incident from the top air side at an angle of \( \theta \) is selected for analysis. The simulated absorption \( (A) \), reflection \( (R) \) and transmission \( (T) \) are performed using the rigorous coupled analysis (RCWA) method [30, 31].

Figure 3 shows the simulated \( R, T \) and \( A \) at normal incidence for the visible region, respectively, where \( p = 280 \) nm, \( F = 0.5, h_1 = 80 \) nm, \( h_2 = 50 \) nm, and \( d = 30 \) nm. As shown in Fig. 2, the average absorption is about 98.4% from 400 to 700 nm and the absorption peak \( (A \approx 99.6\%) \) appears at the wavelength of \( \lambda = 600 \) nm. Figure 3 shows the absorption spectra for TM-polarized light in the visible region with the incident angle varying from 0° to 60°. The average absorption is still over 86.6% when the incident angle adds up to 60°. The above simulation results show that the proposed absorber has robust angle tolerance, which is crucial and needful for the applications in color-printing and harvesting solar energy. Figure 4 shows the absorption spectra of the absorber for different polarization-angles ranging from 0° (TM polarization) to 90° (TE polarization) at normal incidence. Near-perfect absorption from 400 to 700 nm is achieved for all polarization angles, illustrating the polarization independence of the designed structure.
To understand the physical mechanism of the broadband absorption of the proposed absorber, the magnetic field at the absorption peak (λ = 600 nm) and several non-absorption peak positions (λ = 400 nm, 500 nm, and 700 nm) is presented in Fig. 5. From Fig. 5, it is found that the magnetic field is mainly confined within the multilayered structure at these wavelengths. As can be seen from Fig. 5a, at λ = 400 nm, the magnetic field is mainly confined at the interface between the bottom metal layer and the dielectric layer, just below the metal grating groove, indicating the excitation of local surface plasmon resonance (SPRs) [20, 32]. At λ = 500 nm, λ = 600 nm and λ = 700 nm, the effects of the local SPRs at the interface between the bottom metal layer and the dielectric layer underly the metal grating groove are weakened. However, the enhanced magnetic field is mainly located at the region confined by the periodic subwavelength grating ridges and the bottom metal layer. In this case, the SPRs excitation on the lower surface of the subwavelength metal grating and the upper surface of the bottom metal layer and their coupling result in strong absorption [20, 32].

To further analyze the physical mechanism of the proposed absorber, the Poynting vector distributions at λ = 400 nm (non-absorption peak) and λ = 600 nm (absorption peak) for TM-polarized light are presented in Fig. 6. At λ = 400 nm, most of the incident energy flow passes through the grooves of the metal grating into the bottom metal layer, and a small amount of energy flows into the area below the metal grating ridges. At λ = 600 nm, most of the incident energy flows into the area below the metal grating ridges, and part of them flows through this area and then into the bottom metal layer. Finally, the energy will be dissipated by the Ohmic losses of W. Therefore, the designed structure can permit high polarization-independent absorption in the visible regime. Most of the energy is found to be trapped in the multilayered structure, which gives a solid proof that the SPRs play a key role in the absorptive behavior in the structure.

The dependence of the absorption spectra of the TM-polarized light on the period (p), the height (d), and the duty cycle (F) of the subwavelength metal grating are demonstrated in Fig. 7a–c, respectively. As can be seen from Fig. 7a, when the period varies from 250 to 350 nm, the absorption in the whole visible band is about 98.0%. From Fig. 7b, it is indicated that the broadband character is also controlled by d. If d is too large (> 60 nm), the reflection of W will be obvious, leading to a decrease in absorption efficiency. When F varies from 0.4 to 0.6, the proposed structure absorbs efficiently in the whole visible band, as shown in Fig. 7c. From the production feasibility point of view, the best parameter for wide bandwidth is F = 0.5. The dependence of the absorption spectrum of the TM polarized light on the height (h_2) of the dielectric layer is demonstrated in Fig. 7d. It is obvious that h_2 is extremely significant for broadband character. When h_2 is in the range of 20–80 nm, the structure has good broadband absorption performance. When h_2 changes from 80 to 150 nm, the absorption performance decreases sharply, because the coupling of surface plasmon waves decreases. When h_2 is greater than 150 nm, it shows the characteristics of narrow band absorption. From the above analysis, it can be seen that the designed structure has greater tolerance for structural parameters, so it can reduce the rigor of the process.

The influence of metal materials on the absorption performances of the proposed absorber by replacing the W layer by Ti, Cr and Al while keeping the geometry parameters constant is analyzed in Fig. 8a. And the absorption spectrum without the corresponding metal grating layer is shown in Fig. 8b. It can be inferred from Fig. 8a that when using W, Ti or Cr, the absorption spectrum exhibits superior performance with a broadband perfect absorption.
When using Al, the absorption in the visible region is significantly reduced. The discrepancy observed here is decided by the metal’s intrinsic dispersion property. In the proposed structure, for the refractory metal of W, Ti or Cr with an appropriate thickness satisfies the impedance match conditions and thus achieves high absorption in the visible range [33]. In Fig. 8b, it can be seen that when there is no metal grating at the top, the corresponding absorption efficiency decreases significantly. It is further demonstrated that the absorption is enhanced due to the
surface plasmon resonance excited by the metal grating in our proposed structure. Through the detailed analysis above, it is confirmed that the excellent absorption performance mainly comes from the synergy of surface plasma resonance and the inherent broadband spectral response of the refractory metals.

**Conclusion**

In this work, a near-perfect absorber incorporating metal-dielectric-metal subwavelength grating structure with refractory materials is numerically and theoretically analyzed. The average absorption of TM-polarized is 98.4%, and the
peak absorption can reach 99.6%. This excellent absorption performances are due to the synergy of surface plasma resonance and the inherent broadband spectral response of refractory metals. The advantage of this structure is that its absorption performance has good tolerance for structural parameters, which can reduce the strict requirements for manufacturing process. The results of this paper can provide reference for the design of absorbers working in the visible with refractory materials and are expected to find potential applications in structural color, solar-energy harvesting, and other optical devices.
