A B S T R A C T

Leucocytozoonosis is a vector-borne infection of birds, caused by members of the haemosporidian genus Leucocytozoon. The clinical presentation may range from asymptomatic to severe disease. Consequences of Leucocytozoonosis on blood profiles remain to be described, especially for different host species in the wild. In the current study, the prevalence of Leucocytozoonosis was determined for two species of European raptor, the common buzzard (Buteo buteo, n = 464) and the northern goshawk (Accipiter gentilis, n = 18). Among 528 nestlings, 51.9% (n = 274) were infected with Leucocytozoon spp., whereby the highest prevalence was found in common buzzards (54.9%), followed by red kites (32.6%) and goshawks (22.2%). For a subset of 87 individuals (50 common buzzards, 29 red kites, 8 northern goshawks), a detailed analysis of differential leukocyte counts and several blood chemistry parameters in response to infection was conducted: AP (alkaline phosphatase), AST (aspartate aminotransferase), GLDH (glutamate dehydrogenase), LDH (lactate dehydrogenase), GGT (gamma glutamyl transferase), CK (creatine kinase), BuChE (butyrylcholinesterase), BA (bile acids), ALB (albumin) and TP (total protein). Even though in the physiological range, infected nestlings displayed significantly increased levels of heterophils, aspartate aminotransferase, lactate dehydrogenase, bile acids and butyrylcholinesterase, but decreased lymphocyte and monocye values compared to uninfected ones. Furthermore, significant species differences with regard to blood parameters, but no sex differences were found. Overall, obtained results show a high prevalence, but a low pathogenicity of Leucocytozoon spp. in wild raptor chicks, presumably resulting from coevolutionary adaptation, but show signatures of infection in the haematological and blood chemistry profiles.

1. Introduction

Life-threatening malaria is caused by blood parasites of the genus Plasmodium while related haemosporidian parasites of the genera Haemoproteus and Leucocytozoon can cause a suite of similar conditions in diverse vertebrate hosts (Atkinson et al., 2008; Valkiūnas, 2005). These haemosporidian parasites are transmitted by blood-feeding insects and occur in numerous bird species worldwide (Bensch et al., 2009; Clark et al., 2014; Valkiūnas and Iezhova, 2017), whereby Leucocytozoon is particularly widespread in raptors (Krone et al., 2008; Lierz et al., 2002).

Plasmodium, Haemoproteus and Leucocytozoon spp. have been repeatedly associated with considerable pathology in various bird species and clinical signs like anemia, anorexia, depression, neurological disorder, blindness or even sudden death, particularly in weak or injured individuals (Atkinson et al., 2008; Atkinson and van Riper, 1991; Bennett et al., 1993; Donovan et al., 2008; Raida and Jaensch, 2000; Remple, 2004). Infections may lead to tissue damage of several organs (Donovan et al., 2008; Valkiūnas and Iezhova, 2017). However, severe clinical disease may rather be an exception in most wild birds, but systematic studies of haemosporidian infections in wild hosts are scarce.
The complex life cycle of *Leucocytozoon* spp. includes transmission by blood-feeding blackflies (*Simulium*), as well as blood and tissue stages in the bird host (Santiago-Alarcon et al., 2012; Valkiunas, 2005). In contrast to *Plasmodium*, *Leucocytozoon* spp. do not undergo erythrocytic merogony, but initially multiply in hepatocytes (Valkiunas and Ježova, 2017). Further multiplication occurs in numerous organs, with formation of so-called megalomeronts. These often establish in the spleen, while the liver is rarely affected, presumably due to local immunity initiated during hepatic merogony (Valkiunas and Ježova, 2017). Although their exact significance within the developmental cycle is unclear, megalomeronts can lead to an increased size of the affected organ, and potentially impair its functional capacity (Valkiunas, 2005; Valkiunas and Ježova, 2017). In general, haemoparasite infections in wild birds are common and improved knowledge regarding their impact on haematology and blood chemistry values can represent an important tool for diagnostics and treatment in avian medicine (Bensch et al., 2009; Clark et al., 2014; Schoenle et al., 2017). So far, *Plasmodium* and *Haemoproteus* infections have been linked with changes in blood chemistry and haematology in birds (Campos et al., 2014; Dawson and Bortolotti, 1997; Fokidis et al., 2008; Horak et al., 1998; Kraus et al., 2013; Townsend et al., 2018; Williams, 2005), whereas *Leucocytozoon* infections seem to cause only minor or no changes in blood profiles (Raída and Jaensch, 2006; Townsend et al., 2018). Additionally, many *Leucocytozoon* spp. are rather taxon-specific and thought to infect nestlings without causing severe pathology (Chitty and Lierz, 2008). However, it remains to be elucidated whether blood cell count and blood chemistry values reflect infection status and parasitemia of raptors, and indicate how nestlings cope with the infection.

In this study, we examined chicks of three common European raptor species, the common buzzard (*Buteo buteo*), the red kite (*Milvus milvus*) and the northern goshawk (*Accipiter gentilis*), belonging to the family Accipitridae. According to previous studies, these species are more likely to be infected with *Leucocytozoon* than with *Plasmodium* or *Haemoproteus* spp. (Hanel et al., 2016; Krone et al., 2008; Pérez-Rodríguez et al., 2013). Forest raptors show a particularly high *Leucocytozoon* prevalence (Chakarov et al., 2008; Krone et al., 2001; Lierz et al., 2002), presumably because of their habitat overlap with vectors and common within-family transmission (Chakarov et al., 2015, 2020). Due to its abundance, the common buzzard is also one of the most common raptor species presented in veterinary practices in Central Europe, indicating the need for an in-depth investigation of leucocytozoosis in this species (Hatt and Claus, 2016).

The purpose of this study was to investigate *Leucocytozoon* prevalence among wild nestlings of three different raptor species in northwestern Germany and to investigate the effects of the infection on haematological and blood chemistry profiles of these raptors.

2. Materials and methods

2.1. Study site and sampling

The prevalence of *Leucocytozoon* spp. was examined in 528 raptor nestlings belonging to three species, common buzzard (*n* = 464), red kite (*n* = 46) and northern goshawk (*n* = 18). Sampling of nestlings was permitted by the ethics commission of the Animal Care and Use Committee of the German North Rhine-Westphalia State Office for Nature, Environment and Consumer Protection (*Landesamt für Natur, Umwelt und Verbraucherschutz Nordrhein-Westfalen*) under reference number 84-02.04.2017.A1.47.

The study area covers more than 300 km² in Eastern Westphalia, Germany and is characterised by an agricultural landscape interspersed with many small and large forest areas (Krüger, 2004). In March and April 2019, nests of breeding raptors were identified and revisited for sampling between May and July 2019. At the time of sampling, chicks were between two and seven weeks old. All raptor chicks were collected from their nests and lowered to the ground for sampling. Sampling was performed within 30 min as described by Chakarov et al. (2008) before chicks were returned to the nest. Tarsus length was measured with a calliper to the nearest 0.1 mm as well as wing length to the nearest 1 mm with a ruler. Weight was measured with a spring scale (Pesola, Schindellegi, Switzerland) to the nearest 5 g. The age of chicks at sampling was determined from wing length using standard growth curves for the respective species (Bijlsma, 1997; Mammen and Stubbe, 1995). In common buzzards, the sex of the individuals as well as light, intermediate and dark plumage of this polymorphic species was additionally determined (Bijlsma, 1999; Melde, 1995). A blood sample of up to 0.5 ml was taken from the Vena ulnaris of each bird, using a 0.3 mm (30G) x 8 mm needle. Immediately after collection, two blood smears were prepared and air-dried. The remaining blood sample was instantly transferred into 1.3 ml heparinized tubes. The heparinized blood was centrifuged at 2000×g for 10 min (LabNet centrifuge, C1301), and the superficial plasma was stored at −80 °C until further investigation. The remaining cell-rich blood fraction was diluted with 1 ml phosphate buffered saline (PBS) and stored at −20 °C.

2.2. Examination of blood smears

Blood smears were fixed in absolute ethanol within 12 h, dried and stained with 10x diluted Giemsa stock solution (48900, Sigma-Aldrich, St. Louis, USA). All smears were scanned for haemosporidian parasites by light microscopy (Axioskope, Zeiss, Oberkochen, Germany) at 400x magnification. Approximately 10,000 erythrocytes per chick were scanned. Infection intensity was categorized as follows: not infected (no detectable parasites), low (1–10 parasites per 10,000 erythrocytes), medium (>10–100 parasites per 10,000 erythrocytes) and high infection intensity (>100 parasites per 10,000 erythrocytes).

2.3. Haematology and blood chemistry

A subsample of 87 nestlings was chosen for detailed comparison of haematological and blood chemistry parameters between infected and uninfected nestlings. Of these, 44 birds were infected with *Leucocytozoon* spp. (25 common buzzards, 15 red kites and 4 northern goshawks), and 43 were uninfected (25 common buzzards, 14 red kites and 4 northern goshawks). In the 43 uninfected individuals, absence of infection was confirmed via nested PCR, testing haemosporidian infections as described by Pérez-Rodríguez et al. (2013). Briefly, DNA was extracted from the PBS-diluted blood cells using a standard phenol-chloroform protocol (Sambrook et al., 1989). Amplification products were visualized on a 2% agarose gel stained with ethidium bromide. Furthermore, these 87 selected individuals were additionally sexed molecularly using primers 2550F (5′-GTACTGATTCGTCTACGAGA-3′) to amplify the CHD1W (females) and CHD1Z (males) gene as previously described (Fridolfsson and Ellegrén, 1999).

Per sample, 100 leukocytes where differentiated into lymphocytes, granulocytes (heterophils, eosinophils and basophils) and monocytes by morphologic and staining characteristics at 1000x magnification and the heterophil/lymphocyte ratio (H/L) was calculated (Samour, 2006). In order to estimate the total number of leukocytes per microliter blood, the number of cells counted in 10 fields at 400x magnification was multiplied by 2000 (Campbell and Ellis, 2007; Sabater and Forbes, 2014).

Blood chemistry parameters were mainly selected to represent liver function (Harr, 2006; Sabater and Forbes, 2015; Wernery et al., 2004) to detect indications of organ damage caused by developing *Leucocytozoon* meronts. All parameters were analysed by a commercial laboratory (SYNLAB.vet GmbH, Geesthacht, Germany). An AU680 Clinical Chemistry Analyzer (Beckman Coulter, Brea, USA) was used for photometric measurement of the following metabolite concentrations: AP (alkaline phosphatase), AST (aspartate aminotransferase), GLDH (glutamate dehydrogenase), GGT (γ-glutamyl transpeptidase), albumin, globulin, alanine aminotransferase and creatine kinase.
2.4. Statistical analyses

Statistical analyses were conducted using R. v. 4.0.2 (R Core Team, 2020). To determine potential factors influencing Leucocytozoon prevalence among the 528 chicks, a generalized linear mixed model (GLMM) with binomial error structure and logit link function was constructed, including bird species and age as fixed factors. Age was standardized by dividing every value by the species-specific average nesting duration (common buzzard: 45.5 days; northern goshawk: 44 days; red kite: 47.5 days) to account for variations in the length of the nestling phase (Südbeck et al., 2005). This measure is equivalent to the proportion of the entire nestling period that has been spent in the nest at sampling. Furthermore, another GLMM was calculated for the subset of common buzzards only, including the variables sex and plumage morph, which were only available for this species, in addition to body mass as fixed factors. Both models included nest ID as a random intercept to account for the fact that several individuals were sampled per brood. Full models were compared to null models including only the random intercept via likelihood ratio tests (R function “anova”).

A linear discriminant analysis (LDA) was used to investigate whether the measured blood parameters allowed discrimination between infected and non-infected nestlings in the subset of 87 individuals. Furthermore, linear models were constructed to estimate the influence of Leucocytozoon infections on the following blood parameters, which were identified as having high discriminatory power in the LDA: lymphocytes (%), monocytes (%), heterophils (%), eosinophils (%), AST, BA, BuChE, LDH and AP. Response variables were log-transformed, except for eosinophils (%). Bird species, sex and age were included as confounding factors. Interactions between predictor variables were initially included and retained in models if statistically significant (P ≤ 0.05). Multiple comparisons between levels of categorical predictors were conducted based on Tukey contrasts using the function “glht” (R package “multcomp” (Hothorn et al., 2008)) with single-step P-value adjustment. For model validation, normality and homogeneity of residuals was assessed graphically. Furthermore, full models were compared to null models including only an intercept term (R function “anova”). Finally, false discovery rate (FDR) adjustment was applied to all P-values using the Benjamini-Hochberg method.

3. Results

3.1. Prevalence of Leucocytozoon spp. in raptor nestlings

In total, 528 samples were screened for Leucocytozoon spp., comprising 464 common buzzards, 46 red kites and 18 northern goshawks. Leucocytozoon infections were detected in 51.9% (274/528) of all raptor nestlings. Common prevalence in buzzards was 54.9% (255/464), in red kites 32.6% (15/46) and in northern goshawk 22.2% (4/18) (Fig. 1). Among the 274 infected nestlings, 21.5% showed a low, 27.4% a medium and 51.1% a high infection intensity. Regarding the onset of infection, there was a steep increase in the first half of the nestling period, and by the end of this first half, more than 50% of the tested individuals were infected (Fig. 2).

Leucocytozoon prevalence in goshawks and red kites was significantly lower than in common buzzards (GLMM, P = 0.034 and P = 0.013, respectively, Table 1). Furthermore, the likelihood of infection increased with the standardised age (P = 0.027, Table 1). Among the 447 common buzzards for which these variables were available, the effect of standardised age was similar in magnitude, but did not reach statistical significance (P = 0.077). Furthermore, the likelihood of infection was not explained by sex or plumage morph (Supplementary Table 1).

---

Table 1

| Species | Intercept | Std. Error | z   | P     |
|---------|-----------|------------|-----|-------|
| A. gentilis vs. B. buteo | –1.83 | 0.75 | –2.45 | 0.0344 |
| M. milvus vs. B. buteo | –1.23 | 0.44 | –2.79 | 0.0135 |
| M. milvus vs. A. gentilis | 0.60 | 0.84 | 0.72 | 0.7399 |

a Standardised by dividing every value by the species-specific average nesting duration.
b Multiple comparisons between species were conducted based on Tukey contrasts using the function “glht” (R package “multcomp”; Hothorn et al., 2008) with single-step P-value adjustment.

---
3.2. Effects of Leucocytozoon infection on haematological and blood chemistry parameters

Eighty-seven samples were analysed for 12 haematological and 10 blood chemistry parameters. Of the 87 individuals, a total of 48 chicks were identified as male and 39 as female. Among common buzzards, 30 were male and 20 female, among red kites 15 were male and 14 female, and among goshawks 3 were male and 5 female. Obtained haematological values are presented in Table 2, and blood chemistry values in Table 3. Due to the low levels of variation in GLDH and basophil values, these were not considered in this analysis.

Overall, there was a considerable overlap in most blood parameter values between infected and uninfected nestlings (Table 3). However, the LDA indicated that the blood profiles differed slightly between uninfected and infected nestlings (Fig. 3). The variance-covariance matrix was homogeneous and the multivariate distribution of the variables followed a normal distribution. An error rate of 30.1% [standard deviation (SD): 0.78] was estimated in predicting infection status (infected or uninfected) in seven subsets randomly selected from the complete dataset, using a cross validation method.

Based on the LDA result, linear models were employed to quantify the influence of infection on nine predominantly affected blood parameters (lymphocytes, monocytes, heterophils, eosinophils, AST, BA, BuChE, LDH, AP), taking bird species, sex and age into consideration. Significant differences in blood parameter values with respect to infection status were observed for seven parameters (Table 4, Supplementary Table 2). Infection was significantly associated with elevated heterophil, AST, LDH, BA and BuChE, but decreased lymphocyte and monocyte values. Regarding these seven parameters, all were within the species-specific standard range, with the exception of LDH in northern goshawks, where the values of uninfected also deviated from references (Chitty and Lierz, 2008; Gelli et al., 2009; Hanauka-Brown et al., 2003; Hernandez et al., 1990; Stout et al., 2010).

3.3. The influence of sex, species and age on blood parameters of raptor nestlings

Neither infection status nor haematological and blood chemistry parameters differed between male and female nestlings in any of the three raptor species (Table 4). In contrast, species differed significantly regarding all haematological parameters, except lymphocyte proportion. The heterophil fraction was approximately 28% higher in red kites compared to common buzzards (Supplementary Table 2). Red kites also had higher BA values, whereas their eosinophil and BuChE levels were lower than in both common buzzards and northern goshawks. Moreover, significantly lower proportions of monocytes were observed in northern goshawks than in the other two species, while significant differences in AST, AP and LDH levels appeared between all examined species. In addition, age had a significant positive effect on AST, AP and eosinophil counts.

Furthermore, significant interaction effects were detected. In older raptor chicks, the effect of Leucocytozoon infections on AST was weaker than in younger individuals. Also, the difference in monocyte levels between northern goshawks and common buzzards decreased with age in both infected and uninfected nestlings. In red kites, the effect of Leucocytozoon infections on LDH was smaller compared to buzzards. No apparent sex-infection interactions appeared to explain any additional variation in blood parameters.

4. Discussion

Studies on the prevalence of Leucocytozoon and other haemosporidian parasites in raptors are numerous and mostly suggest high prevalence, in some cases up to 100% (Jeffries et al., 2015; Valkiunas, 2005). Recent studies have shown Leucocytozoon infections to be highly prevalent also in passerine species with similar or shorter altiracial periods than the studied raptors (Schmid et al., 2017; Schum et al., 2019; Shurulinkov et al., 2018). In this study, Leucocytozoon infections were detected in nestlings of all three studied raptor species, as expected from related results (Bensch et al., 2009). Preliminary genetic data showed that in all three species the infecting parasites belonged to the Leucocytozoon todi-group. The genetic lineages represented in kites and buzzards were MILANS04 and MILYUS01, while ACGE02 of the species Leucocytozoon mathisi was responsible for the infections of goshawks (unpublished results). Since at the end of the first half of the nesting period more than 50% of the at this time examined nestlings tested positive, transmission by simulid vector appears to be very effective in the first weeks of life. Another interesting finding was that 51% of all infected nestlings showed a high infection intensity. However, haemosporidian prevalence and infection intensities can be quite variable between years, geographic locations and depend mostly on the occurrence of vectors (Isaksson et al., 2013; Shurulinkov and Chakarov, 2006; Sol et al., 2000; Yohannes et al., 2009). Seasonal effects can also be of great importance, as adult birds affected by stress and sexual hormones can experience spring relapses during the breeding season, thus facilitating parasite transmission to the offspring (Ashford et al., 1990; Krone et al., 2001).

Among the raptor species, we observed significantly higher infection rates in common buzzards (55%) compared to 33% in red kites and 22% in northern goshawks. This confirms previous studies showing a substantially higher Leucocytozoon prevalence in buzzards than in kites (Krone et al., 2001; Lierz et al., 2002). This difference may result from the different habitat niches used by these sympatric species, as the microhabitats used by buzzards in our study area are also preferred by simulid vectors of Leucocytozoon spp. (Chakarov et al., 2020). Although black flies occur almost globally, the specific habitat and location of the

a Heterophil/lymphocyte ratio.
An increasing risk of infection with addition to species differences, the spent nestling period significantly has been shown for common buzzards and sparrowhawks before, age has been shown for common buzzards and sparrowhawks before, and there is substantial variation of reference values between species, even between closely related ones, are common. Nevertheless, with the exception of eosinophilic and LDH of northern goshawks, these prevalences are subject to greater uncertainty. In host selection (Chakarov et al., 2021).

Blood parameter analyses revealed significant differences in blood cell counts and blood chemistry values between the three study species as well as correlations with age, whereas sex did not appear to affect examined blood parameters. However, blood parameter differences between species, even between closely related ones, are common (Fudge, 2000) and there is substantial variation of reference values within each species [e.g. Hernandez et al. (1990), Gelli et al. (2009) for common buzzards; Hanauska-Brown et al. (2003), Stout et al. (2010) for northern goshawks]. Besides species variations, we found significant blood parameter differences between uninfected raptor chicks and those infected with Leucocytozoon species. Nevertheless, with the exception of eosinophilic and LDH of northern goshawks, significantly differing values were still within the described standard range, if available for these species (Chitty and Lierz, 2008; Gelli et al., 2009; Hanauska-Brown et al., 2003; Hernandez et al., 1990; Gelli et al., 2009; Hanauska-Brown et al., 2003; Hernandez et al., 1990; Stout et al., 2010). However, since Leucocytozoon prevalence is usually high in most Accipitriformes populations, it is important to note that such infections may increase the variation of within- and between-population reference values.

In mammals, parasitaemia leads to an increase of eosinophilic granulocytes (Behn and Ovington, 2000; Dombrowicz and Capron, 2000), but several exceptions exist (Dey et al., 2010; Schmid et al., 2017). Overall, variability in the infection prevalence of different raptor species requires further research, e.g. with regard to the preferences of blackflies in host selection (Chakarov et al., 2021).

Blood parameter analyses revealed significant differences in blood cell counts and blood chemistry values between the three study species as well as correlations with age, whereas sex did not appear to affect examined blood parameters. However, blood parameter differences between species, even between closely related ones, are common (Fudge, 2000) and there is substantial variation of reference values within each species [e.g. Hernandez et al. (1990), Gelli et al. (2009) for common buzzards; Hanauska-Brown et al. (2003), Stout et al. (2010) for northern goshawks]. Besides species variations, we found significant blood parameter differences between uninfected raptor chicks and those infected with Leucocytozoon species. Nevertheless, with the exception of eosinophilic and LDH of northern goshawks, significantly differing values were still within the described standard range, if available for these species (Chitty and Lierz, 2008; Gelli et al., 2009; Hanauska-Brown et al., 2003; Hernandez et al., 1990; Gelli et al., 2009; Hanauska-Brown et al., 2003; Hernandez et al., 1990; Stout et al., 2010). However, since Leucocytozoon prevalence is usually high in most Accipitriformes populations, it is important to note that such infections may increase the variation of within- and between-population reference values.

In mammals, parasitaemia leads to an increase of eosinophilic granulocytes (Behn and Ovington, 2000; Dombrowicz and Capron,
lymphocytes and monocytes despite the infection. Regarding monocytes, we show considerable changes in our study, most likely due to decreased monocyte levels in infected chicks, while overall levels of WBCs in infected chicks did not differ from infected chicks. However, the above reference values are based on adult birds, and eosinophil proportion was not significant after FDA correction. Nevertheless, we presume that a variety of different factors influence blood chemistry values.

In contrast to leucocytozoonosis, infections with the genus Plasmodium have been shown to induce stronger effects on blood parameters in birds (Townsend et al., 2018; Williams, 2005). Potentially, this may be due to significantly different, these are not in the range indicating serious organ damage. Based on the overall rather minor shifts in blood parameters in our study, we expect that a variety of different factors influence blood chemistry values.

Our study demonstrates an increase of AST and AP production in older chicks, corresponding to increasing consumption and production during growth (Harr, 2006; Joseph, 1999). While values of LDH significantly differed between infected and uninfected chicks, the direction was not consistent between species. Therefore, this parameter cannot be generalized as informative of infection status across species. Based on interactions between infection, species and age, we also suspect that a variety of different factors influence blood chemistry values.

Regarding blood chemistry profiles, the enzymes selected in the present study do not have a known function in the vascular system, so elevated levels are typically used as indicators of increased synthesis or tissue damage (Printzinger et al., 2012). To differentiate between liver and muscle damage, AST and LDH should be evaluated in combination with CK (Sabater and Forbes, 2015). We found a significant increase of AST and LDH but not CK in infected nestlings, representing an indication for liver cell damage (Wernery et al., 2004). However, as already mentioned, most values were within the wide standard range for these raptors (Gelli et al., 2009; Stout et al., 2010). Less frequently evaluated but strongly specific, increased levels of BA along with AST, as detected in infected nestlings in the present study, provide further indication of liver dysfunction (Horowitz et al., 2016). However, preceding food intake, for which we could not control, is known to have a considerable impact on BA levels (Lumeij, 1997; Lumeij and Remple, 1992). A significant postprandial increase occurs in birds as well as mammals, as BA is released from the gall bladder for intestinal fat digestion (Lumeij, 1997). Nevertheless, liver damage can be differentiated from food intake by significantly higher values (Gray et al., 2008), but reference values of plasma BA are not yet available for most bird species.

We tested for differences in plasma BA and LDH concentrations in nine individual blood parameters among species and age groups. While values of LDH significantly differed between infected and uninfected chicks, the direction was not consistent between species. Therefore, this parameter cannot be generalized as informative of infection status across species. Based on interactions between infection, species and age, we also suspect that a variety of different factors influence blood chemistry values.

5. Conclusions

The present study showed leucocytozoonosis to be highly prevalent in raptor nestlings, especially in common buzzards. However, according to the blood profile results, the pathogenicity of the parasite appears to be only low. In addition to differences in blood parameters between uninfected and infected individuals, we also found variance with age and among raptor species. Future long-term studies are necessary to evaluate further and prolonged effects of Leucocytozoon infections in fledged raptor hosts.
