Abstract

We study observational constraints on the cosmic evolution of the relationships between massive black hole (MBH) mass ($M_\ast$) and stellar mass ($M_{\ast,sph}$; or velocity dispersion $\sigma$) of a host galaxy/spherial. Assuming that the $M_\ast - M_{\ast,sph}$ (or $M_\ast - \sigma$) relation evolves with redshift as $\propto (1 + z)^3$, the MBH mass density can be obtained from either the observationally determined galaxy stellar mass functions or velocity dispersion distribution functions over redshift $z \sim 0$–1.2 for any given $\Gamma$. The MBH mass density at different redshifts can also be inferred from the luminosity function of QSOs/active galactic nuclei (AGNs) provided the radiative efficiency $\epsilon$ is known. By matching the MBH density inferred from galaxies to that obtained from QSOs/AGNs, we find that $\Gamma = 0.64^{+0.27}_{-0.29}$ for the $M_\ast - M_{\ast,sph}$ relation and $\Gamma = -0.21^{+0.28}_{-0.33}$ for the $M_\ast - \sigma$ relation, and $\epsilon = 0.11^{+0.04}_{-0.03}$. Our results suggest that MBH mass growth precedes bulge mass growth but that the galaxy velocity dispersion does not increase with mass growth of the bulge; however, activity is quenched, which is roughly consistent with the two-phase galaxy formation scenario proposed by Oser et al. in which a galaxy roughly doubles its mass after $z = 1$ due to accretion and minor mergers while its velocity dispersion drops slightly.

Key words: black hole physics – galaxies: active – Galaxy: evolution – quasars: general

1. Introduction

The masses of massive black holes (MBH; $M_\ast$) are tightly correlated with the properties of the spheroidal components of their host galaxies, such as velocity dispersion $\sigma$ (e.g., Gültekin et al. 2009; Gebhardt et al. 2000; Ferrarese & Merritt 2000; Tremaine et al. 2002; Graham et al. 2011), luminosity $L_{\ast,sph}$ (e.g., Kormendy & Richstone 1995; McLure & Dunlop 2001), and stellar mass $M_{\ast,sph}$ (Magorrian et al. 1998; McLure & Dunlop 2002; Marconi & Hunt 2003; Haring & Rix 2004), which suggests a strong link between the growth of MBHs and the evolution of their host galaxies (or, particularly, galaxy spheroids). Feedback from nuclear activity is proposed as being responsible for the establishment of these relationships, either through momentum or energy-driven winds, to self-regulate MBH growth (e.g., Silk & Rees 1998; Fabian 1999; King 2003; Wyithe & Loeb 2003; Murray et al. 2005; di Matteo et al. 2005; Croton et al. 2006; Bower et al. 2006; Somerville et al. 2008). However, detailed physics on how the feedback mechanism works is not yet clear.

Observational determination of the cosmic evolution of the relations between $M_\ast$ and $M_{\ast,sph}$ (or $\sigma$ or $L_{\ast,sph}$) may reveal important clues about the origin of these relations and may place constraints on potential feedback mechanisms (Shields et al. 2003; Peng et al. 2006; Woo et al. 2006; Treu et al. 2007; Salviander et al. 2007; Woo et al. 2008; Alexander et al. 2008; Somerville 2009; Ksak & Kojima 2010; Merloni et al. 2010; Sarria et al. 2010; Bennert et al. 2010, 2011; Cisternas et al. 2011; Schulze & Wisotzki 2011; Portinari et al. 2012; Li et al. 2012a). A number of studies have shown that the $M_\ast - M_{\ast,sph}$ relation in active galactic nuclei (AGNs) evolves with redshift (or cosmic time), $\alpha (1 + z)^3$, where $\Gamma \sim 0.68 \pm 2.1$ (e.g., Merloni et al. 2010; Bennert et al. 2011). Tentative observational evidence also suggests that the $M_\ast - \sigma$ relation may evolve with redshift as well (e.g., Woo et al. 2006, 2008). In most of those studies, MBH masses are derived by adopting the virial mass estimators, which are based on the mass estimates of several dozen MBHs in nearby AGNs through the reverberation mapping technique and a calibration of those masses to the $M_\ast - \sigma$ relation obtained for nearby normal galaxies (e.g., Onken et al. 2004; Graham et al. 2011). However, MBH mass estimated from virial mass estimators may suffer from some systematic biases for various reasons (e.g., Krolik 2001; Collin et al. 2006; Netzer & Marziani 2010; Kollatschny & Zetzl 2011; Graham et al. 2011); moreover, the MBHs in AGNs are still growing rapidly, unlike those in nearby quiescent galaxies. Therefore, it is not yet clear whether the cosmic evolution of the $M_\ast - M_{\ast,sph}$ relation and the $M_\ast - \sigma$ relation found for AGNs is biased or not and whether the relations for normal galaxies have a similar cosmic evolution as those for AGNs.

In this paper, we adopt an alternative method of investigating the cosmic evolution of the $M_\ast - M_{\ast,sph}$ and $M_\ast - \sigma$ relations in normal galaxies by matching the MBH mass density inferred from normal galaxies at different redshifts with that inferred from AGNs. The evolution of the $M_\ast - M_{\ast,sph}$ and $M_\ast - \sigma$ relations for normal galaxies is assumed to follow a simple power-law form, i.e., $\propto (1 + z)^{\Gamma}$. In Section 2, we estimate the evolution of the MBH mass density in normal galaxies in two ways: (1) using the stellar mass functions (SMFs) of galaxies determined by recent observations over the redshift range $z \sim 0$–1.2 (e.g., Bernardi et al. 2010; Ilbert et al. 2010) and (2) using the velocity dispersion functions (VDFs) of galaxies at $z \sim 0$–1.5 (Bernardi et al. 2010; Bezanson et al. 2011). The evolution of the estimated MBH densities depends on the parameter $\Gamma$. According to the simple Sołtan (1982) argument, the MBH mass density evolution can also be derived from the AGN luminosity functions (LFs), as shown in Section 2.3, where the parameter $\Gamma$ is not involved. By matching the MBH density evolution inferred from properties of normal galaxies to that inferred from AGNs, the cosmic evolution of the $M_\ast - M_{\ast,sph}$ (or $M_\ast - \sigma$) relation is then constrained in Section 3. Our discussion and conclusions are given in Sections 4 and 5.

Throughout the paper, we adopt the cosmological parameters $H_0 = 70.5$ km s$^{-1}$, $\Omega_\Lambda = 0.726$, and $\Omega_M = 0.274$ (Komatsu 2011).
et al. 2009). The mass is in units of $M_\odot$ and the velocity dispersion is in units of km s$^{-1}$. Given a physical variable $X$ (e.g., mass, logarithm of mass, mass velocity distribution), the $X$ function is denoted by $n_X(X, z)$ so that $n_X(X, z)dX$ represents the comoving number density of the objects (e.g., MBHs or galaxies) with variable $X$ in the range $X \rightarrow X + dX$ at redshift $z$.

2. THE MASS DENSITY EVOLUTION OF MASSIVE BLACK HOLES

2.1. The Mass Density of Massive Black Holes Inferred from Stellar Mass Functions

The mass of an MBH in the center of a nearby ($z \sim 0$) normal galaxy can be estimated through the $M_*-M_{*,\text{sph}}$ relation at $z = 0$, i.e.,

$$\langle \log M_* \rangle (M_{*,\text{sph}}; z = 0) = (8.20 \pm 0.10) + (1.12 \pm 0.06) \times \langle \log M_{*,\text{sph}} \rangle - 11,$$

(1)

where $\langle \log M_* \rangle (M_{*,\text{sph}}; z = 0)$ is the mean value of the logarithmic MBH masses for galaxies with spheroidal mass $M_{*,\text{sph}}$ and the intrinsic scatter of $\langle \log M_* \rangle (M_{*,\text{sph}}; z = 0)$ around this mean value is 0.3 dex (Haring & Rix 2004; see also McLure & Dunlop 2002). Currently, there is still no consensus on the $M_*-M_{*,\text{sph}}$ relation for galaxies at high redshift. In general, the $M_*-M_{*,\text{sph}}$ relation may evolve with redshift and the evolution may be simplified by

$$\langle \log M_* \rangle (M_{*,\text{sph}}; z) = \langle \log M_* \rangle (M_{*,\text{sph}}; z = 0) + \Gamma \log(1+z),$$

(2)

as assumed in a number of previous works (e.g., Merloni et al. 2010; Bennert et al. 2011), where the parameter $\Gamma$ describes the significance of the evolution, and the intrinsic scatter of the relations is assumed not to evolve with redshift.

The mass function of MBHs (BHMF) at redshift $z$ may be estimated by adopting the $M_\star-\log M_{*,\text{sph}}$ relation (Equation (2)) and the SMF of spheroids at that redshift if the SMF can be observationally determined, i.e.,

$$n_{\log M_*}(\log M_*, z) = \int n_{\log M_{*,\text{sph}}}(\log M_{*,\text{sph}}, z) \times P(\log M_*; \langle \log M_* \rangle) d \log M_{*,\text{sph}},$$

(3)

where $n_{\log M_{*,\text{sph}}}(\log M_{*,\text{sph}}, z)$ is the SMF of spheroids at redshift $z$, $P$ is the probability density function of $\log M_*$ around $\langle \log M_* \rangle$ and is assumed to be normally distributed with a dispersion of 0.3 dex. The SMF of spheroids at redshift $z$ can be estimated by using the SMFs for galaxies with different morphological types and the bulge-to-total mass ratios $B/T$, i.e.,

$$\sum_i \int \frac{d \log M_{*,\text{sph}}}{d \log M_*} n_{\log M_{*,\text{sph}}}(\log M_{*,\text{sph}}, z) f_i(M_{*,\text{tot}}, z) d \log M_{*,\text{tot}},$$

(4)

where $M_{*,\text{tot}} = M_{*,\text{sph}}/(B/T)$, $n_{\log M_{*,\text{sph}}}(\log M_{*,\text{sph}}, z)$ is the SMF for all galaxies, $n_{\log M_{*,\text{sph}}}(\log M_{*,\text{sph}}, z)$ is the SMF for the spheroids of those galaxies with Hubble type $i$, $f_i(M_{*,\text{tot}}, z)$ is the fraction of galaxies with Hubble type $i$ to all galaxies, and the summation is over galaxy morphological types from E, S0, Sa-Sh, Sc-Sd to Irr.

The SMFs for galaxies at $z \sim 0$ with different morphological types have been obtained from the Sloan Digital Sky Survey (SDSS; Bernardi et al. 2010, see Table B2 therein). The bulge-to-total mass ratio $B/T$ has been obtained by Weinzierl et al. (2009, see Table 1) for more than a hundred nearby galaxies with different Hubble types. In summary, the bulge-to-total mass ratios are 1, 0.28 ± 0.02, 0.46 ± 0.05, 0.35 ± 0.10, 0.22 ± 0.08, 0.15 ± 0.05, and 0 for E, S0, Sa, Sab, SB, Sc-Sd, and Irr, respectively. Adopting these observations, the SMFs of spheroids and the BHMFs at $z = 0$ can be estimated.

For galaxies at redshift $z \sim 0.2–1.2$, the total SMFs have been obtained by Ilbert et al. (2010), Pérez-González et al. (2008), Fontana et al. (2006), and Borch et al. (2006). These SMFs are usually obtained from deep surveys with small sky coverage and may suffer cosmic variance. To avoid cosmic variance, we adopt the average total SMFs according to the SMFs estimated in the above papers. In Ilbert et al. (2010), the SMFs of quiescent early-type galaxies (E+S0) at different redshifts are directly obtained (see Table 2 therein); we obtain the SMFs of all the galaxies by summing the SMFs of early-type galaxies and those of “intermediate-activity” and “high-activity” galaxies (see the definitions of “intermediate activity” and “high activity” in Ilbert et al. 2010, and see their Table 3). We assume that the fraction of early-type galaxies at any given mass is the same as that given by Ilbert et al. (2010) and hereafter adopt this fraction, together with the average total SMFs, to calculate the MBH mass function for early-type galaxies. The LFs of galaxies were estimated by Zucca et al. (2006) for four different spectral types, which roughly correspond to morphological types E/S0, Sa-Sb, Sc-Sd, and Irr, respectively. For each type of galaxy, the mass-to-light ratio can be estimated through their average colors, for instance, $\log(M_\star/\text{L}_\text{B}) = -0.942 + 1.737(B-V) + 0.15$ for early-type galaxies by adopting the Salpeter initial mass function and $\log(M_\star/\text{L}_\text{B}) = -0.942 + 1.737(B-V) - 0.10$ for late-type galaxies by adopting the Chabrier initial mass function (Bell & De Jong 2001; Bell et al. 2003; Bernardi et al. 2010; Chabrier 2003). The $B-V$ colors for different morphological types of galaxies are given by Fukugita et al. (1995). The luminosity evolution can be corrected for each type of galaxy according to Bell et al. (2003). The LF for galaxies with different morphological types (Zucca et al. 2006) can thus be converted to the SMFs. According to these SMFs, the relative abundance of different late-type galaxies (Sa-Sb, Sc-Sd, and Irr) over $z \sim 0.2–1.2$ can be obtained at any given $M_\star$. The SMFs of spheroids and the BHMFs can then be estimated if the $B/T$ is, on average, the same for galaxies with the same spectral type (and perhaps, accordingly, the same morphological type) but at different redshifts. Consequently, the mass density accreted onto MBHs with mass $M_\star$ can be obtained by

$$\rho_\star(\rho \to 0): >M_\star = \int_{M_\star}^\infty (M_\star - M_{*,\text{sph}}) n_{\log M_*}(\log M_*, z) d \log M_*,$$

(5)

if mergers of MBHs do not significantly contribute to the MBH growth and the seeds of those MBHs are smaller than $M_\star$ (see Equation (29) in Yu & Lu 2004 and Equation (35) in Yu &
The probability density function of log the BHMF at redshift $z$ is estimated from the given a constant $\epsilon$.

The hard X-ray AGN LF has been estimated by a number of authors based on surveys by ASCA, Chandra, and XMM in the past decade (e.g., Ueda et al. 2003; La Franca et al. 2005; Silverman et al. 2008; Ebrero et al. 2009; Yencho et al. 2009; Aird et al. 2010). In this paper, we adopt the latest 2–10 keV X-ray AGN LF obtained by Aird et al. (2010), the LADE model in their Table 4) over the redshift range $0 < z < 3.5$ and extrapolate it to higher redshifts. Adopting other versions of the 2–10 keV AGN LF has little effect on the results presented in the following section. The BCs in the hard X-ray band (2–10 keV, denoted as $C_X$) have been found to be luminosity-dependent and the BC at any given bolometric luminosity has already been derived by Marconi et al. (2004) and Hopkins et al. (2007). To obtain the MBH mass density from the AGN LF, we need to estimate the probability distribution function of $P(C_Y | L_Y)$. Hopkins et al. (2007) obtained the probability distribution function of $C_Y$ as a function of $L_{bol}$. By adopting the same procedures as those in Hopkins et al. (2007), we fit the BCs by a log-normal distribution with the following parameters: $c_1$, $k_1$, $k_2$, $c_2$, and $\sigma_{log C_X}$

$$\langle \log C_X \rangle = \log \left[ c_1 \left( \frac{L_X}{10^{38} \text{erg s}^{-1}} \right)^{k_1} + c_2 \left( \frac{L_X}{10^{38} \text{erg s}^{-1}} \right)^{k_2} \right],$$

where $c_1$, $k_1$, $k_2$, $c_2$, and $\sigma_{log C_X}$ are the galaxy VDF at redshift $z$, $P$ is the probability density function of log $M_\bullet$ around $\langle \log M_\bullet \rangle (\sigma; z = 0)$ and is assumed to be normally distributed with a dispersion of 0.44 dex. The VDF for local galaxies has been estimated from SDSS (Bernardi et al. 2010, see Table B4 therein). At higher redshifts $z \sim 3–1.5$, the VDFs have been obtained from the UKIDSS Ultra-Deep Survey and the NEWFIRM Medium Band Survey (Bezanson et al. 2011). Adopting those VDFs, the BHMFs and, consequently, the mass density accreted onto MBHs with masses larger than $M_\bullet$ can also be estimated (see Equation (5)).

2.2. The Mass Density of Massive Black Holes Inferred from Velocity Dispersion Distribution Functions

The mass of an MBH can also be estimated through the $M_\bullet - \sigma$ relation at redshift $z = 0$, i.e.,

$$\langle \log M_\bullet (\sigma; z = 0) = (8.12 \pm 0.08) + (4.24 \pm 0.41) \times (\log \sigma - 2.30) \rangle,$$

with an intrinsic scatter of 0.44 dex (Gültekin et al. 2009). Assuming an evolutionary form similar to Equation (2), i.e.,

$$\langle \log M_\bullet (\sigma; z) = \langle \log M_\bullet (\sigma; z = 0) + \Gamma \log (1 + z), \rangle,$$

the BHMF at redshift $z$ can be estimated through

$$n_{log M_\bullet}(M_\bullet, z) = \int n_{gal}^\text{vdf}(\sigma, z) P(\log M_\bullet; (\log M_\bullet)) d\sigma,$$

where $n_{gal}^\text{vdf}(\sigma, z)$ is the galaxy VDF at redshift $z$, $P$ is the probability density function of log $M_\bullet$ around $\langle \log M_\bullet \rangle (\sigma; z)$ and is assumed to be normally distributed with a dispersion of 0.44 dex. The VDF for local galaxies has been estimated from SDSS (Bernardi et al. 2010, see Table B4 therein). At higher redshifts $z \sim 3–1.5$, the VDFs have been obtained from the UKIDSS Ultra-Deep Survey and the NEWFIRM Medium Band Survey (Bezanson et al. 2011). Adopting those VDFs, the BHMFs and, consequently, the mass density accreted onto MBHs with masses larger than $M_\bullet$ can also be estimated (see Equation (5)).

2.3. The Mass Density of Massive Black Holes Inferred from AGNs

The MBH mass density at redshift $z$ can also be inferred from the LFs of AGNs according to the simple Soltan (1982) argument as MBHs obtained their masses mainly through gas accretion (e.g., Salucci et al. 1999; Yu & Tremaine 2002; Marconi et al. 2004; Yu & Lu 2004, 2008; Shankar et al. 2004, 2009), i.e.,

$$\rho_{\bullet}^\text{AGN}(z > M_\bullet) \sim \int_0^{\infty} dz \int dL_Y \int dC_Y \frac{1 - \epsilon}{\epsilon^2} \times C_Y P(C_Y | L_Y) L_Y \phi(L_Y, z) \left| \frac{dt}{dz} \right|,$$

where $L_Y$ is the AGN Y-band luminosity, $\phi(L_Y, z)$ is the AGN Y-band LF, $\epsilon$ is the mass-to-energy conversion efficiency, $C_Y \equiv L_{bol}/L_Y$ is the bolometric correction (BC) for the Y band, with $L_{bol}$ being the AGN bolometric luminosity, and $P(C_Y | L_Y) dC_Y$ gives the probability of a BC being in a range $C_Y \rightarrow C_Y + dC_Y$ given an $L_Y$. The hard X-ray LFs of AGNs are adopted here because a significant number of obscured AGNs can be detected only in the hard X-ray band and are missed in optical surveys. Using the hard X-ray AGN LF and the corresponding BC, the MBH mass density can be estimated given a constant $\epsilon$.

4 Since Compton-thick AGNs are not included in the hard X-ray AGN LF, which may be a fraction of $\sim 20\%$ of the total AGN population (Malizia et al. 2009), the MBH mass densities inferred from the AGN LFs above may be underestimated by 20% and thus $\epsilon$ for the best match is underestimated by a factor of $\sim 1.2$.

5 We adopt the QSO spectral energy distribution (SED) model constructed by Hopkins et al. (2007). For details, the template SED consists of a power law in the optical-UV band, i.e.,

$$L_\nu \propto \nu^{-\alpha},$$

where $\alpha \equiv -0.44$ for $1 \mu$m $< \lambda < 1300 \AA$ and $\alpha \equiv -1.76$ from 1200 $\AA$ to 500 $\AA$. At wavelengths longer than $\lambda > 1 \mu$m, an infrared “bump” from reprocessing of optical-UV-X-ray emission is adopted and truncated as a Rayleigh–Jeans tail of the blackbody emission ($\sigma_c$). The typical Eddington ratio for low-luminosity AGNs is around 0.1 (Shen et al. 2008) or 0.2 (Graham et al. 2011), it is reasonable to set the lower limit as $L_{bol}(M_\bullet) \sim 0.1L_{edd}(M_\bullet)$ or $0.2L_{edd}(M_\bullet)$. Our calculations show that the difference in the lower limit does not lead to a significant difference in the results.
3. CONSTRAINTS ON THE COSMIC EVOLUTION OF THE $M_\ast-M_{sph}$ RELATION AND THE $M_\ast-\sigma$ RELATION

In this section, we obtain constraints on the evolution of the $M_\ast-M_{sph}$ (or $M_\ast-\sigma$) relation by matching the MBH densities inferred from normal galaxies with that from AGNs using standard $\chi^2$ statistics, i.e.,

$$
\chi^2 = \sum_i \frac{[\rho_{gal}^{\ast}(z_i, > M_\ast) - \rho_{AGN}^{\ast}(z_i, > M_\ast)]^2}{[\delta \rho_{gal}^{\ast}(z_i, > M_\ast)]^2 + [\delta \rho_{AGN}^{\ast}(z_i, > M_\ast)]^2},
$$

where $z_i$ is the $i$th redshift bin and the summation is over all the redshift bins, $\delta \rho_{gal}^{\ast}(z_i, > M_\ast)$ and $\delta \rho_{AGN}^{\ast}(z_i, > M_\ast)$ are the uncertainties in the MBH mass densities estimated from the normal galaxies and AGNs, respectively, considering the 1$\sigma$ errors in most of the fitting parameters for the SMFs/VDFs and the AGN LFs, and the $M_\ast-M_{sph}$ and $M_\ast-\sigma$ relations. The errors in the normalizations of the $M_\ast-M_{sph}$ and $M_\ast-\sigma$ relations and the AGN LF only introduce systematic shifts of all the estimates but do not lead to a change in the shape of the cosmic evolution of the MBH density; therefore, we do not include them in $\delta \rho_{gal}^{\ast}(z_i, > M_\ast)$ and $\delta \rho_{AGN}^{\ast}(z_i, > M_\ast)$ in the $\chi^2$ fitting here.

Figure 1 shows the mass densities of those MBHs with masses $>10^6 M_\odot$ estimated from the SMFs of normal galaxies, which are best matched by the MBH densities estimated from the hard X-ray AGN LFs. The corresponding parameters for the best match are $(\Gamma, \epsilon) = (0.64^{+0.23}_{-0.27}, 0.11^{+0.03}_{-0.02})$ and the errors are obtained for each parameter by marginalizing over the other parameters. According to our calculations, a $\Gamma$ larger than 1.6 is excluded at the 3$\sigma$ level. The value of $\Gamma = 0.65$ suggests that the $M_\ast-M_{sph}$ relation evolves positively with redshift, i.e., the relative positive offset of the $M_\ast-M_{sph}$ relation at redshift $z$ to that in the local universe increases with increasing redshift. Figure 2 shows the MBH mass densities estimated from the VDFs of normal galaxies, which are also best matched by the MBH densities estimated from the hard X-ray AGN LFs. The corresponding parameters for the best match are $(\Gamma, \epsilon) = (-0.21^{+0.28}_{-0.33}, 0.12^{+0.02}_{-0.01})$, which suggests that the $M_\ast-\sigma$ relation does not evolve with redshift. The $\epsilon$ obtained by adopting the $M_\ast-\sigma$ relation is larger because the MBH densities at $z \sim 0$ estimated from the $M_\ast-\sigma$ relation are smaller than those from the $M_\ast-M_{sph}$ relation. Considering the 1$\sigma$ errors in the normalizations of the $M_\ast-M_{sph}$ and $M_\ast-\sigma$ relations and the AGN LF, there are the additional errors $\pm 0.03$ in the estimated $\epsilon$. By combining these additional errors with the errors obtained from the above $\chi^2$ fitting and averaging the $\epsilon$ obtained from the two relations, we have $\epsilon = 0.11^{+0.04}_{-0.03}$, which is consistent with the constraint obtained in Yu & Lu (2008).

As seen from Figures 1 and 2, the MBH mass density at $z \sim 0$ is about $(3.5-4) \times 10^6 M_\odot$, which may be slightly smaller than that obtained by others (e.g., Graham & Driver 2007; Shankar et al. 2009). This difference is mainly due to the difference in the normalization of the adopted $M_\ast-\sigma$ relation and different treatment on the dependence of the MBH mass density on the Hubble constant. These differences lead to a change of the MBH density estimates at different redshifts by the same factor, but the shape of the MBH density evolution does not change and thus the constraint on $\Gamma$ is not affected.

In the above calculations of the MBH mass densities, the SMFs and VDFs are extrapolated to the low-mass or low-velocity dispersion end, of which part may be not accurately determined by the observations at all the redshifts considered in this paper (see Ilbert et al. 2010; Bezanson et al. 2011). To see whether the final results are affected by the extrapolation, we also set the lower limit of the MBH mass to $10^6 M_\odot$ and redo the above matching. We find $(\Gamma, \epsilon) = (0.61^{+0.21}_{-0.20}, 0.18^{+0.02}_{-0.02})$ to match the MBH mass densities estimated from the SMFs of normal galaxies with that estimated from the AGNs, and find $(\Gamma, \epsilon) = (-0.62^{+0.20}_{-0.20}, 0.19^{+0.02}_{-0.02})$ to match the MBH mass densities estimated from the VDFs of normal galaxies. The constraints on $(\Gamma, \epsilon)$ for MBHs with mass $>10^6 M_\odot$ are roughly consistent with that for MBHs with mass $>10^6 M_\odot$.
4. DISCUSSION

The positive evolution of the $M_\ast-M_{\ast,sph}$ relation found in this paper is consistent with that found by Merloni et al. (2010; see also Jahnke et al. 2009 and Bennert et al. 2011) and that predicted by Booth & Schaye (2011), which suggests that the growth of MBHs predates the assembly of spheroids and the spheroids experience additional growth after the quench of their central nuclear activities. The non-evolution of the $M_\ast-\sigma$ relation found here appears different from the positive evolution found by Woo et al. (2006, 2008). We note here that this difference may be lessened as the MBH masses estimated in Woo et al. (2006, 2008) may be overestimated by a factor of two as suggested by the uncertainties in the virial factor recently revealed by Graham et al. (2011). However, the exact reason for this difference is not clear as our results are obtained through the global evolution of the MBH mass densities, which is different from the method adopted in Woo et al. (2006, 2008) for a sample of individual AGNs/QSOs. The VDFs estimated by Bezanson et al. (2011) are the very first estimates of VDFs at redshift $z \neq 0$, and may suffer from various uncertainties as discussed in Bezanson et al. (2011). If the non-evolution of the $M_\ast-\sigma$ relation is true, nevertheless, it suggests the velocity dispersion of galactic bulges does not increase; although the masses of the bulges can be significantly enlarged after the quench of their central nuclear activities.

The evolution of the relations between the MBH mass and galaxy properties is investigated theoretically in the scenario of co-evolution of galaxies and MBHs since the discovery of these scaling relations. For those early models that adopt rapid and strong feedback due to energy output from the central AGNs which terminates star formation, the scaling relations are expected to evolve little and have very small scatters (e.g., Granato et al. 2004; Robertson et al. 2006; di Matteo et al. 2005; Springel et al. 2005). Later models do suggest that the $M_\ast-M_{\ast,sph}$ relation evolves positively with redshift though with various degrees of evolution (e.g., Hopkins et al. 2007; Croton et al. 2006; Malbon et al. 2007; Lamastra et al. 2010), by considering detailed dissipation processes occurring during major mergers of galaxies and the acquiring of bulge masses by dynamical processes such as disk instabilities or disrupting stellar disks. However, the expected $M_\ast-\sigma$ relation is almost independent of redshift (Hopkins et al. 2007). Apparently the constraints that we obtained in this paper are roughly consistent with the theoretical studies of Hopkins et al. (2007). Furthermore, we note that Oser et al. (2010; see also Oser et al. 2012) have recently proposed a two-phase galaxy formation scenario, in which galaxies roughly double their masses after $z = 1$ due to accretion and minor mergers while velocity dispersion drops slightly. If MBHs mainly obtained their masses through efficient accretion triggered by major mergers, then our constraints are consistent with the two-phase galaxy formation scenario.

4.1. Mass-to-energy Conversion Efficiency in AGNs/QSOs

The constraints on $\Gamma$ obtained above may depend on the use of a constant $\epsilon$, i.e., $\epsilon$ is independent of $M_\ast$, redshift, and other physical quantities involved in the accretion processes. We argue that the use of a constant $\epsilon$ in AGNs/QSOs is appropriate as follows: (1) $\epsilon$ is determined mainly by the spins of MBHs in the standard disk accretion scenario; (2) the majority of the AGNs/QSOs are accreting via thin disks with high Eddington ratios ($\gtrsim 0.1$); and (3) the spins of individual MBHs can quickly reach an equilibrium value and stay at that value for most of the AGN lifetime as suggested by theoretical models (e.g., Volonteri et al. 2005; Shapiro 2005; Hawley et al. 2007; Maio et al. 2012), which suggests a roughly constant $\epsilon$ at all redshifts. Note that according to recent observations, some authors such as Davis & Laor (2011), Martínez-Sansigre & Rawlings (2011), and Li et al. (2012b) introduced a dependence of $\epsilon$ on the redshift or MBH mass. However, these results may be due only to some observational biases (e.g., Raimundo et al. 2012) and need further investigation. Nevertheless, we note here that one could also introduce a cosmic evolution to $\epsilon$ before understanding the underlying physics. For example, if we assume $\epsilon(z) = \max(0.057, \min(\epsilon_0(1+z)^\kappa, 0.31))$ and the $M_\ast-M_{\ast,sph}$ relation does not evolve with redshift, where $0.31$ and $0.057$ are the $\epsilon$ that an efficiently accreting MBH-disk system could reach if the MBH spin is either 0.998 (the maximum spin of an MBH; see Thorne 1974) or 0 (a Schwarzschild MBH). In this case, an acceptable fit can also be found and the best-fit...
AGNs are an integration of... than at $z \sim 0$. However, the MBH densities estimated from AGNs are an integration of $d\rho MBH/dz$ over $z$, and $d\rho MBH/dz$ is a function of $\epsilon(z)$ and has to be determined to high redshift. The MBH densities estimated from the SMFs in this paper only cover redshifts up to $\sim 1.2$ and may poorly constrain the evolution of $\epsilon(z)$ at higher $z$. If $\epsilon$ is significantly higher at higher redshifts, a significantly negative evolution in the $M_\bullet-\sigma$ relation is required. Future measurements of the SMFs and VDFs at $z \gtrsim 1.2$ may help to determine the MBH densities at higher $z$ and thus may help to place further constraints on whether $\epsilon$ significantly evolves with redshift.

To close the discussion on this issue, we remark here that the constraint on the cosmic evolution of the $M_\bullet-M_{sph}$ (or $M_\bullet-\sigma$) relation obtained in this paper is robust if the efficiency $\epsilon$ of the efficient accretion processes in QSOs/AGNs is roughly a constant, which may be true as suggested by some physical models of the spin evolution of MBHs (e.g., Volonteri et al. 2005; Shapiro 2005; Hawley et al. 2007; Maio et al. 2012).

4.2. Intrinsic Scatters in the $M_\bullet-M_{sph}$ or the $M_\bullet-\sigma$ Relation

The intrinsic scatters in the $M_\bullet-M_{sph}$ and $M_\bullet-\sigma$ relations have been assumed not to evolve with redshift in obtaining the constraints on the cosmic evolution of the relations. If the intrinsic scatter in the $M_\bullet-M_{sph}$ relation increases significantly with increasing redshift, the parameter $\Gamma$ can still be consistent with 0 to match the MBH densities estimated from normal galaxies to that from AGNs. To settle onto the observed local $M_\bullet-M_{sph}$ relation with a smaller intrinsic scatter but with the same normalization, however, it is necessary for those galaxies at a fixed $M_{sph}$ with relatively large MBHs to accrete more stars and for those with relatively small MBHs not to accrete many stars after nuclear activity is quenched. This is not likely to be the case for the stochastic increasing of $M_{sph}$ due to minor mergers or other dynamical processes such as disk instabilities.

In addition, we note that estimation of the intrinsic scatter of the $M_\bullet-M_{sph}$ (or $M_\bullet-\sigma$) relation must determine the measurement errors in both the MBH and stellar masses, and it is still challenging to accurately determine these measurement errors (see discussions in Graham et al. 2011). Graham (2012) shows that the total scatter could range from 0.44 dex to 0.7 dex for different types of galaxies (see Table 1 therein).

4.3. Alternative $M_\bullet-M_{sph}$ or $M_\bullet-\sigma$ Relation

In the analysis in Section 3, we adopt the single power-law form for the $M_\bullet-M_{sph}$ relation given by Häring & Rix (2004). Recently, Graham (2012) suggested that this relation may be better described by a broken power law than the single power law shown in Equation (1). To determine the effects of this new development on the constraints obtained above, here we replace the $M_\bullet-M_{sph}$ relation at $z = 0$ shown in Equation (1) by the broken power-law form given in Graham (2012), i.e., $(\log M_\bullet(M_{sph}, z = 0) = (8.38 \pm 0.17) + (1.92 \pm 0.38) \log M_{sph}/(7 \times 10^{10} M_\odot))$ at $M_{sph} < 7 \times 10^{10} M_\odot$ and $(8.40 \pm 0.37) + (1.01 \pm 0.52) \log M_{sph}/(7 \times 10^{10} M_\odot))$ at $M_{sph} > 7 \times 10^{10} M_\odot$, respectively. Similarly, we also assume that the intrinsic scatter of this relation is 0.3 dex. By performing the same analysis as in Section 3, we obtain constraints on $(\Gamma, \epsilon)$ of $(0.44^{+0.74}_{-0.75}, 0.06^{+0.04}_{-0.01})$. The best-fit value of $\Gamma = 0.44$ is still consistent with that obtained in Section 3 $(0.64^{+0.27}_{-0.29})$ within 1σ error but its uncertainty $(^{+0.74}_{-0.75})$ is large. Compared with the constraints on $(\Gamma, \epsilon)$ obtained for the single power-law $M_\bullet-M_{sph}$ relation, the larger uncertainty of $\Gamma$ obtained here is mainly because of the relatively larger uncertainties in the slope of the broken power-law $M_\bullet-M_{sph}$ relation adopted here lead to larger uncertainties in the estimations of the MBH mass densities compared with that for the single power-law $M_\bullet-M_{sph}$ relation adopted above. The $\epsilon$ obtained here (0.06) is also substantially smaller than that obtained for the single power-law $M_\bullet-M_{sph}$ relation, mainly because of the relatively higher zero point of the broken power law given by Graham (2012).

In the analysis in Section 3, we also adopt the single power-law form for the $M_\bullet-\sigma$ relation given by Gültekin et al. (2009), which is largely consistent with those estimated by others (see references therein). Recently, Graham et al. (2011) updated the $M_\bullet-\sigma$ relation and found that this relation may be different for barred galaxies than for non-barred galaxies/ellipticals. If we assume that the $M_\bullet-\sigma$ relation is the same as that for ellipticals at $\sigma > 180\ km\ s^{-1}$ (i.e., $(\log M_\bullet/\sigma; z = 0) = (8.22 \pm 0.09) \pm (5.30 \pm 0.77) \log(\sigma/200\ km\ s^{-1})$ with an intrinsic scatter of 0.29) and the same as that for barred galaxies at $\sigma \sim 180\ km\ s^{-1}$ (i.e., $(\log M_\bullet/\sigma; z = 0) = (8.15 \pm 0.06) \pm (5.95 \pm 0.44) \log(\sigma/200\ km\ s^{-1})$ with an intrinsic scatter of 0.35; see Table 2 in Graham et al. 2011), we find $(\Gamma, \epsilon) = (-0.86^{+0.31}_{-0.30}, 0.14^{+0.03}_{-0.01})$. The constraint obtained here for $\Gamma$ is substantially different from that obtained in Section 3, which suggests a significant negative evolution of the velocity dispersion of individual big galaxies, i.e., the velocity dispersions of big galaxies decrease by $\sim 20\%$, which is marginally compatible with the hierarchical galaxy formation scenario recently proposed by Oser et al. (e.g., 2010, 2012). However, the $\epsilon$ obtained here is slightly higher than that obtained above for a single power-law $M_\bullet-\sigma$ relation, which is mainly due to the smaller intrinsic scatter of the adopted $M_\bullet-\sigma$ relation and the smaller normalization for the relation at $\sigma < 180\ km\ s^{-1}$. Both of those factors lead to slightly smaller MBH mass densities in all the redshift bins and hence slightly higher $\epsilon$.

5. CONCLUSIONS

In this paper, we study the cosmic evolution of the $M_\bullet-M_{sph}$ and $M_\bullet-\sigma$ relations by a global method, independent of individual MBH mass estimates. We have estimated the cosmic evolution of MBH mass densities over the redshift range $z \sim 0$–1.2. The MBH mass densities are estimated from both the SMFs/VDFs of normal galaxies determined by recent observations using the $M_\bullet-M_{sph}$ and $M_\bullet-\sigma$ relations, and the AGN X-ray LFs according to the simple Soltan (1982) argument. By matching the MBH densities estimated from the normal galaxies with those from the AGN X-ray LFs, we obtain global constraints on the evolution of the $M_\bullet-M_{sph}$ and $M_\bullet-\sigma$ relations. We find that the $M_\bullet-M_{sph}$ relation evolves positively with redshift, i.e., $\alpha(1+z)^{\gamma}$ and $\Gamma = 0.64^{+0.27}_{-0.29}$, though the significance level is not high; however, a $\Gamma$ larger than 1.6 is excluded at the 3σ level. We also find that the $M_\bullet-\sigma$ relation appears not to evolve positively with redshift $(\Gamma = -0.21^{+0.28}_{-0.28})$. Our results suggest that MBH mass growth precedes bulge mass growth but that galaxy velocity dispersion does not increase with the mass growth of the bulge after nuclear activity is quenched, which is roughly consistent with the two-phase galaxy formation scenario proposed by Oser et al. (2012) in which a galaxy roughly doubles its masses after $z = 1$ due to accretion and minor mergers while its velocity dispersion drops slightly.
