Abstract: Human cerebellum plays a vital role in motor coordination, regulation of muscle tone and maintaining the equilibrium of the body. It seldom shows anatomical/morphological variations. Herein, we report the presence of a small additional lobe projecting out on the superior surface of the right cerebellar hemisphere in the para-vermal area in an adult male cadaver. There was a notch on the tentorial surface of the occipital lobe of the right cerebral hemisphere, corresponding to the additional lobe of cerebellum. The additional lobe was histologically normal, with no evidence of any tumour cells. Knowledge of this variation is of importance to radiologists, neuroanatomists and neurosurgeons.

rior cerebellar artery, the anterior inferior cerebellar artery and the posterior inferior cerebellar artery. These arteries originate from vertebro-basilar arterial system [5]. Very few anomalies/variations of cerebellum have been reported. Herein, we report a unique additional lobe of cerebellum and discuss about it clinical relevance.

Case Report

During dissection classes for medical undergraduates, a rare variation of the cerebellum was observed in an adult male cadaver aged about 65 years. The brain was well-preserved and looked anatomically normal. However, we noticed a small additional lobe projecting out from the superior surface on to the right cerebellar hemisphere in the paravermal area (Figs. 1, 2). This additional lobe was somewhat spherical, with a narrow medial end. The narrow medial end of this lobe was attached to the folium of the superior vermis. The additional lobe was resting on the superior semilunar lobule. It measured 2 cm each in height and breadth. The additional lobe had normal morphology as the other parts of the cerebellum with no evidence of tumour on any part of the cerebellum. The blood supply of the additional lobe was derived from the superior cerebellar vessels. The inferior surface of occipital lobe of the right cerebral hemisphere presented a notch reciprocal to the additional lobe of cerebellum. We processed the additional lobe for the routine H&E staining and observed it under the light microscope (Olympus U-CMAD3, T7; Olympus, Tokyo, Japan) for presence of any abnormalities. Photomicrographs were taken at 10X magnification. Microscopic anatomy of the additional lobe showed normal layers and cells of cerebral cortex. The medulla (white matter) was also normal histologically (Fig. 3). There were no associated variations in the tentorium cerebelli. We do not have the history about the health and lifestyle of the individual before death.
Discussion

Anatomical abnormalities of cerebellum, such as presence of additional lobes are extremely rare. In the past, a cerebellar vermal abnormality has been observed in an 11-year-old female patient during MRI scanning. An extra vermis attached to the anterior lobe of the native vermis, mainly to the culmen was observed in this case. Herniation of anterior superior folia of this extra-cerebellar tissue had occurred superiorly through the left side of the tentorial notch. The extra-vermis had a primary fissure and a pre-pyramidal fissure [6].

A case of duplication of a unilateral cerebellar hemisphere associated with a complex ipsilateral ear anomaly was reported by Jackson et al. [7]. Another reported anomaly of cerebellum was a case of supernumerary hemi-cerebellum in an adult female patient who presented with headaches and episodes of syncope was reported by Hattapoğlu et al. [8]. In another study, a bony outpouching with a small defect in the bone outline on the left side was found on CT examination. This outpouching had third cerebellar hemisphere, which appeared to be only mildly dysplastic and was attached to the medulla on the right side (Table 1) [9].

Knowledge of the process of early fetal cerebellar development helps in understanding of cerebellar variation and malformation. Unfortunately, most of the studies on the cerebellar development are from rodents. Human studies on development of cerebellum are very few. During the fifth week of gestation, thickening occurs bilaterally in the alar plate of the rhombencephalon, forming the rhombic lips, which are the primordia of the cerebellar hemispheres [10, 11]. The neuroepithelial zones, in the roof of the fourth ventricle and the rhombic lips, are the location of germinal matrices, where the cells of the cerebellum and many brain stem nuclei will form. On fusion of the developing hemispheres at the midline during the ninth gestational week cerebellar vermis formed, fusion then continues inferiorly as the hemispheres grow [10, 12]. According to the recent studies [13, 14] on developing foetuses aged from 6 to 15 weeks, it was noted that the hemispheres and the vermis develop independent of each other. The hemispheres develop from 7th to 9th week of gestation by the protruding rhombic lips, whereas, the vermis develops in the midline area after 12th week of gestation. The formation of the current additional lobe would have occurred during this stage of union between the median vermis and the lateral hemisphere. However, the exact cause for formation of this additional lobe is yet to be understood as there is no report regarding such a lobe hitherto.

The current case is unique and defers considerably from the previously reported cases. The additional lobe projecting from the superior surface would not have caused any functional problems to the individual since it was small and histologically normal. The corresponding notch in the occipital lobe of the cerebrum was possibly a coincident because there was no upward stretching of the tentorium cerebelli, corresponding to the additional lobe. Knowledge of this case could be important to radiologists and neurosurgeons. Presence of additional lobes like this could lead to diagnostic dilemmas during radiological examination.
