ABSTRACT

The accuracy of theoretical mass, radius, and effective temperature values for M-dwarf stars is an active topic of debate. Differences between observed and theoretical values have raised the possibility that current theoretical stellar structure and evolution models are inaccurate towards the low-mass end of the main sequence. To explore this issue, we use the CHEOPS satellite to obtain high-precision light curves of eclipsing binaries with low-mass stellar companions. We use these light curves combined with the spectroscopic orbit for the solar-type companion to measure the mass, radius, and effective temperature of the M-dwarf star. Here, we present the analysis of three eclipsing binaries. We use the PYCHEOPS data analysis software to fit the observed transit and eclipse events of each system. Two of our systems were also observed by the TESS satellite – we similarly analyse these light curves for comparison. We find consistent results between CHEOPS and TESS, presenting three stellar radii and two stellar effective temperature values of low-mass stellar objects. These initial results from our on-going observing programme with CHEOPS show that we can expect to have ~24 new mass, radius, and effective temperature measurements for very low-mass stars within the next few years.

Key words: techniques: photometric – techniques: spectroscopic – binaries: eclipsing – stars: fundamental parameters – stars: low-mass.

1 INTRODUCTION

Understanding the host star is one of the most crucial parts of exoplanet characterization. Exoplanets are most commonly observed and analysed through how they affect the stellar signal, such as with the transit and radial velocity methods (Santos et al. 2020). A more accurate measurement of host size and mass thus leads to more accurate values of planetary size and mass. The host star’s properties are most commonly obtained by finding the closest fit between observable star properties and stellar evolution models (e.g. Baraffe et al. 1998; Dotter et al. 2008). Therefore, any uncertainty in these models leads to systematic errors in the inferred stellar and exoplanetary properties. This has become a potential issue regarding low-mass star systems’ recent popularity as targets for exoplanet observation (Charbonneau & Deming 2007; Quirrenbach et al. 2014; Gillon et al. 2017; Delrez et al. 2018). Low-mass star systems suffer
from a lack of data compared to more massive stars because they are intrinsically much fainter and, hence, harder to study. There is a shortfall in direct and precise mass and radius measurements of these systems, with effective temperature measurements being rarer still. The EBLM project (Triand et al. 2013) was launched to address this lack of fundamental data for M-dwarfs. Hundreds of eclipsing binaries with low-mass companions have been identified using data from the WASP project (Pollacco et al. 2006), and we have measured the spectroscopic orbits for the primary stars in more than 100 of these EBLM systems (Triaud et al. 2017). These data are used to select targets for further study to address lack of precise mass, radius, and temperature measurements for low-mass stars, especially below 0.3 solar masses.

A number of studies have reported inconsistencies between the observed radii and M-dwarfs and theoretically predicted radii from models of low-mass stars, an effect commonly called radius inflation (e.g. Casagrande, Flynn & Bessell 2008; Torres, Andersen & Giménez 2010; Spada et al. 2013; Kesseli et al. 2018). Typically, the measured radii are larger than the predicted values for stars of a given mass by a few percent (e.g. Morales et al. 2009). There is also a tendency for M-dwarfs to be cooler than predicted by models, such that the luminosity of the star is approximately correct. It is currently unclear to what extent radius inflation is due to problems with stellar models, or is the result of bias in the observed radius estimates. Possible sources of error from the models involve uncertainties in the input physics of the model, its initial chemical composition and in convection efficiency (Tognelli, Prada Moroni & Degl’Innocenti 2018; Fernandes et al. 2019). These would in turn provide an uncertainty to predicted radius. It is also possible that some models are missing some physical process that affects the stellar radius. The presence of a strong magnetic field or magnetic activity could inhibit the convective energy transport present in lower-mass stars (Chabrier, Gallardo & Baraffe 2007). This could result in the inflation effect, as the star attempts to maintain a constant energy flux through the surface. Rotation in eclipsing binaries has also been proposed as a potential cause. Tidal interactions between the two bodies in the system could increase the speed of the internal stellar dynamo leading to increased activity (Ribas 2006). Radius inflation therefore could be an observational bias caused by using eclipsing binaries to obtain radii from M-dwarfs. However, cases of long-period eclipsing binaries (Irwin et al. 2011) and isolated M-dwarfs (Spada et al. 2013; Van Grootel et al. 2018) showing similar inflation to short-period eclipsing binaries casts doubt on tidal interactions being the sole cause. The effect of metallicity on very low-mass stars is also debated as a possible cause for inflation with its effect being the sole cause. The effect of metallicity on very low-mass stars is also debated as a possible cause for inflation with its effect being the sole cause. The effect of metallicity on very low-mass stars is also debated as a possible cause for inflation with its effect being the sole cause.

The CHEOPS mission (Benz et al. 2021) is the first small (S-class) European Space Agency mission. Launched on the 18th of December 2019, it has been designed primarily to perform ultrahigh-precision photometry of bright stars that are known to host exoplanet systems. The CHEOPS guaranteed-time observing programme includes a small number of ‘Ancillary Science’ programmes, where the stars observed do not host exoplanets, but where the observations made are relevant to exoplanet science. This includes our programme to use the capabilities of CHEOPS to explore the radius inflation problem. Additionally, in measurements of M-dwarf effective temperature in EBLM systems, there is the possibility of some unrealized systematic error, with different studies reporting widely different results for the same object (e.g. Gómez Maqueo Chew et al. 2014; Swane et al. 2020). Through obtaining high precision observations of secondary eclipses we can compare to previous observations and explore any potential systematic effect.

In this paper, we present our analysis of the first three targets in our CHEOPS programme with a complete set of observations – EBLM J1741+31, EBLM J1934–42, and EBLM J2046 + 06. EBLM J1741+31 and EBLM J1934–42 have also been observed by the TESS satellite (Ricker et al. 2015). This gives us an opportunity to test the reliability of our methods to measure mass, radius, and effective temperature by comparing the results from the two instruments. Our observations, data reduction and methods to characterize the host star are outlined in Section 2. The analysis of the light curves and results are described in Section 3. We discuss our results in the context of previous mass, radius, and effective temperature measurements for M-dwarfs in Section 4, and give our conclusions as to the future prospects for our observing programme in Section 5.

2 OBSERVATIONS AND METHODS

Our three targets are all detached eclipsing binary stars in which a solar-type star is eclipsed by an M-dwarf. The log of our observations is given in Table 1. The observations were made as part of the CHEOPS Guaranteed Time Observation (GTO) programme ID-037: Eclipsing binaries with very low-mass stars. This programme seeks to observe primary and secondary eclipses of 25 EBLM systems. CHEOPS observes stars from low-Earth orbit, so observations are interrupted by occultation of the target by the Earth and passages through the South Atlantic Anomaly. These gaps in the light curve can be up to 44 and 19 min, respectively.

The raw data were processed using version 13 of the CHEOPS data reduction pipeline (DRP; Hoyer et al. 2020). The DRP performs image correction for environmental and instrumental effects before performing aperture photometry of the target. As explained in Hoyer et al. (2020), the Gaia DR2 catalogue (Gaia Collaboration et al. 2018) is used by the DRP to simulate an observations’ field of view (FoV) in order to estimate the level of contamination present in the photometric aperture. The DRP also accounts for the rotating FoV of CHEOPS, where other stars in the image can create ‘smear’ trails and contaminate the photometric aperture. The smear effect is corrected by the DRP, while the contamination produced by nearby stars is recorded in the DRP data products, allowing the user to include or ignore the contamination correction provided. The final photometry
is extracted by the DRP using three different fixed aperture sizes labelled ‘RINF’, ‘DEFAULT’ and ‘RSUP’ (at radii of 22.5, 25.0 and 30.0 pixels, respectively) and a further ‘OPTIMAL’ aperture whose size is dependent upon the FoV contamination. The observed and processed data are made available on the Data Analysis Center for Exoplanets (DAEC) web platform. We downloaded our data from DAEC using PyCHEOPS, a Python module developed for the analysis of data from the CHEOPS mission (Maxted et al. 2021). We fitted the light curves from all four apertures and found that different choice of aperture radius has a negligible impact on the results. Therefore, for EBLM J1741+31 and EBLM J1934–42, we selected the aperture radius that gave the minimum median absolute deviation (MAD) of the point-to-point differences in the light curve of the eclipse visit. We then used the chosen aperture type for the respective transit visits. For EBLM J2046+06 this criterion resulted in slightly different aperture radii for the two visits from the preferred OPTIMAL aperture (25.0 and 26.0 pixels), so we used the DEFAULT aperture instead.

The TESS survey is split into overlapping 90° × 24° deg sky sectors over both northern and southern hemispheres with each sector being observed for approximately one month. EBLM J1741+31 (TIC 18319090) was observed in Sectors 25 and 26 of the survey as part of the Guest Investigator programmes G022156 and G022253, with 2-min cadence data made available. EBLM J1934–42 (TIC 143291764) was observed in Sectors 13 and 27 of the survey as part of the Guest Investigator programmes G011278 and G03216, with 2-min cadence data made available. Data were reduced by the Science Processing Operations Center Pipeline (SPOC; Jenkins et al. 2016) and made available from the Mikulski Archive for Space Telescopes (MAST) web service. We used the Pre-search Data Conditioned Simple Aperture Photometry (PDCSAP) flux data for our analysis. Any cadences in the light curve with severe quality issues were ignored using the ‘default’ bitmask 175 (Tenenbaum & Jenkins 2018). The TESS light curve of EBLM J1741+31 shows a smooth variation with an amplitude ≈0.2 per cent in the flux between the transits. To remove this variability, we divided the light curve by a low-order polynomial fitted by least-squares to the data between the transits. EBLM J1934–42 shows variability in the TESS light curve with an amplitude of about 1 per cent on time-scales of a few days. This may be due to moderate stellar activity modulated by stellar rotation. To remove this low-frequency noise, we fit the data between the transits with a Gaussian process (GP) calculated using the CELERITE (Foreman-Mackey et al. 2017) software package. The kernel of the GP is the stochastically driven damped simple harmonic oscillator function defined by Foreman-Mackey et al. We then divide the entire light curve by the GP predicted by the best-fitting hyperparameters.

The spectroscopic stellar parameters (Teff, log g, microturbulence (ξ), [Fe/H]) and respective uncertainties were estimated by using ARES+MOOG, following the same methodology as described in Sousa (2014) and Santos et al. (2013). For this, we used the combined spectra from the individual observations done with SOPHIE for EBLM J1741+31 and with HARPS observations from ESO programme 1101.C-0721 for EBLM J1934–42 and EBLM J2046+06. For EBLM J1741+31, there were 13 individual observations with SOPHIE, with a signal-to-noise ratio (SNR) of 20–50. The combined spectrum has a total SNR ∼140. For EBLM J1934–42, there were 24 individual observations, with SNR varying between 15–20. The combined spectra has a total SNR ∼100. For EBLM J2046+06, there were 22 individual observations, with SNR varying between 50 and 80. The combined spectra has a total SNR ∼300. We used the ARES code4 (Sousa et al. 2007, 2015) to measure equivalent widths (EW) of iron lines measured using the list of lines presented in Sousa et al. (2008). A minimization process assuming ionization and excitation equilibrium is used to find convergence for the best set of spectroscopic parameters. In this process, we use a grid of Kurucz model atmospheres (Kurucz 1993) and the radiative transfer code MOOG (Sneden 1973).

The radii of the three targets was determined using an adapted infrared flux method (IRFM; Blackwell & Shalils 1977) via relationships between the bolometric flux, the stellar angular diameter, the effective temperature, and the parallax, recently detailed in Schanche et al. (2020). For each target, and using a Markov chain Monte Carlo (MCMC) approach, we built spectral energy distributions (SEDs) from the ATLAS Catalogues (Castelli & Kurucz 2003), using the stellar spectral parameters derived above as priors. Subsequently, we conducted synthetic photometry by convolving the SEDs with the throughput of the selected photometric bandpasses and compared the resulting fluxes with the observed fluxes in these bandpasses; Gaia G, G_B, and G_Rp, 2MASS J, H, and K, and WISE W1 and W2 (Skrutskie et al. 2006; Wright et al. 2010; Gaia Collaboration et al. 2020) to obtain the stellar bolometric fluxes and hence the angular diameters. These diameters were combined with offset-corrected Gaia EDR3 parallaxes (Lindegren et al. 2020) to produce the stellar radii given in Table 2.

The stellar mass M∗ and age t∗ were inferred from two different stellar evolutionary models, namely the PARSEC5 v1.2S code (Marigo et al. 2017) and the CLES code (Code Li`egeois d’Evolution Stellaire;
Table 2. The observed stellar properties of the primary star of our binary targets. Right ascension (RA) and declination (Dec.) are coordinates with equinox J2000.0.

3 ANALYSIS

We analyse the CHEOPS light curves for each star in two steps. In the first step, we analyse each CHEOPS visit in order to determine initial values for our model parameters, and to determine which nuisance parameters must be included in the model to deal with instrumental noise. In the second step, we analyse all the data for each star in a single MCMC analysis to obtain our final results. These results are then compared to an MCMC analysis of TESS data when available.

The output from the light-curve analysis is then combined with an estimate of for the mass of the primary star and $K$ to determine the mass and radius of the M-dwarf. The depth of the secondary eclipse is used together with model SEDs to estimate the effective temperature of the M-dwarf.

3.1 CHEOPS visit-by-visit analysis

To create the models needed for light-curve fitting, we used PYTHON. The transit model uses the gpower2 algorithm (Maxted & Gill 2019) to calculate the transit light curve, assuming a power-2 limb darkening law. The parameters used in the model are the time of mid-primary eclipse $T_{\text{por}}$, the transit depth $D = k^2 R_2^2 R_1^2$, where $R_2$ and $R_1$ are the radii of the secondary and primary stars; $b = \cos i R_1$, where $i$ is the orbital inclination and $a$ is the semimajor axis; $W = \sqrt{(1+k)^2-b^2 R_1/(\pi a)}$; the eccentricity and argument of periastron-dependent parameters $f_1 = \sqrt{e}\sin(\omega)$ and $f_2 = \sqrt{e}\cos(\omega)$; the eclipse depth $L$ and the limb-darkening parameters $h_1$ and $h_2$ as defined by Maxted (2018). For an eclipsing binary with a circular orbit, $D, W,$ and $b$ are the depth, width (in phase units), and impact parameter of the eclipse, respectively. For each target, we obtained one primary and one secondary eclipse so the orbital period, $P$, has to be fixed at a known value. For EBLM J1741+31 and EBLM J1934–42, we fixed $P$ to the value obtained from our analysis of the TESS light curve. For EBLM J2046+06, we fixed the orbital period at the value reported by Martin et al. (2019). To better constrain our fit, Gaussian priors were put on $f_c$ and $f_i$, using $e$ and $\omega$ measurements from the spectroscopic orbit. The orbital eccentricity of EBLM J1934–42 is very small, so we assumed a circular orbit for our analysis. For EBLM J1741+31 and EBLM J1934–42, which have partial eclipses, the eclipses do not constrain the limb darkening properties of the star so we place Gaussian priors on $h_1$ and $h_2$. These priors are listed in Table 3.

The values of $h_1$ and $h_2$ appropriate for the values of [Fe/H], $T_{\text{eff}}$, $R_1$, and $\log g$ given in Section 2 are found using interpolation in the data tables presented in Maxted (2018) based on the limb-darkening profiles from the STAGGER-grid (Magic et al. 2015). An offset (0.01 for $h_1$, $-0.045$ for $h_2$) was then applied based on the offset between empirical and tabulated values of these limb darkening parameters observed in the Kepler bandpass by Maxted (2018).

CHEOPS light curves can be affected by trends correlated with satellite roll angle, the varying contamination of the photometric aperture, the background level in the images, and the estimated
correction for smear trails from nearby stars. These trends are modelled using linear decorrelation against these parameters, or for roll angle $\phi$, $\sin(\phi)$, $\cos(\phi)$, $\sin(2\phi)$, etc. The coefficients for each trend are optimized simultaneously with the parameters of the transit or eclipse model in a least-squares fit to all the data in each visit. In the case of the eclipse events, fits to individual visits were performed with all orbital parameters apart from eclipse depth fixed at the parameters derived from the fit to the transit. To select decorrelation parameters for each visit, we did an initial fit to each light curve with no decorrelation and used the rms of the residuals from this fit, $\sigma_p$, to set a normal prior on the decorrelation parameters, $N(0, \sigma_p)$ or, for $df/dt$, $N(0, \sigma_p/\Delta t)$ where $\Delta t$ is the duration of the visit. We then added decorrelation parameters to the fit one by one, selecting the parameter with the lowest Bayes factor $B_p = e^{-L(\phi)/\sigma_p^2} \sigma_0/\sigma_p$ at each step, where $\sigma_0$ is the standard error on the decorrelation parameter from the least-squares fit (Maxted et al. 2021). We stop adding decorrelation parameters when $B_p > 1$ for all remaining parameters. This process sometimes leads to a set of parameters including some that are strongly correlated with one another and so are therefore not well determined; i.e., they have large Bayes factors. We therefore go through a process of repeatedly removing the parameter with the largest Bayes factor if any of the parameters have a Bayes factors $B_p > 1$. The second step of this process typically removes no more than one or two parameters.

3.2 CHEOPS MultiVisit analysis

We used the MULTIVISIT function in PYCHEOPS to do a combined analysis of both visits for each target. Decorrelation against trends with roll angle were done implicitly using the method described in Maxted et al. (2021), i.e. by modifying the calculation of the likelihood to account for the decorrelation against roll angle without explicitly calculating the nuisance parameters $df/d\sin(\phi)$, $df/d\cos(\phi)$, etc. The same Gaussian priors for $f_1$ and $h_1$, $h_2$ were used as for the analysis of individual visits. For EBLM J1741+31, we also set a prior on the eclipse depth $L$ and on the log of the stellar density $\log \rho$, which is directly related to the transit parameters via Kepler’s law (Maxted et al. 2021). This target has no detectable secondary eclipse and the primary eclipse is very shallow so the model parameters are poorly constrained by the light curve alone. The prior on eclipse depth was set using the predicted flux ratio. This ratio was calculated using the predicted absolute $G$-band magnitude, $M_G$, for each star based on their masses using the calibration by Pecaut & Mamajek (2013). The scatter around the $M_G$-mass relation for $M$-dwarfs was assumed to be similar to the observed scatter in $M_V$ magnitude values reported by Hartman et al. (2015). The prior for $\log \rho$ was calculated, using the derived values of mass and radius described in Section 2. The values used for these priors are shown in Table 3.

The joint PPD for the model and nuisance parameters are sampled, using the sampler emcee (Foreman-Mackey et al. 2013). The initial parameters of the run were the values previously obtained by the fits to the individual visit. We sampled a chain of 128 walkers each going through 35 000 steps after a ‘burn-in’ of 1024 steps to ensure that the sampler has converged to a steady state. To ensure adequate sampling, we ensured that the number of steps chosen was more than 50 times longer than the autocorrelation length of each fitted parameter chain. For EBLM J1934–42, this required a second run of emcee with 180 000 steps, and for EBLM J1741+31, a second run with 240 000 steps with a ‘burn-in’ of 8192 steps. To ensure independent random samples from their posterior probability distributions, each parameter chain was thinned by approximately half the minimum parameter autocorrelation length. The parameter values given in Table 4 are the median value of the parameters from the sampled PPD and the standard errors are estimated from the 15.9 per cent and 89.1 per cent percentile-points in the distribution for each parameter. The fitted decorrelation parameters from our analyses are shown in Appendix A in Table A1. Correlations between selected parameters are displayed in Appendix B. In EBLM J1741+31, there are strong correlations between $D$, $W$ and $b$ as can be seen in Fig. B1. In EBLM J1934–42, the correlation between these parameters is not as strong though there are a significant number of walkers that tend to larger values of $D$ and $b$ as can be seen in Fig. B2. In EBLM J2046+06 as shown in Fig. B3, there is again a correlation between $D$, $W$ and $b$, but not as strongly as for EBLM J1741+31. The light-curve fit and residuals for these parameter values are shown in Fig. 1.

3.3 TESS light curve analysis

We have compared our results using CHEOPS data to a similar analysis of the TESS light curves for EBLM J1741+31 and EBLM J1934–42. For EBLM J1741+31, we used data from TESS sectors 25 and 26 covering five transits. For EBLM J1934–42, we used data from sectors 13 and 27 covering 6 transits. Sampling of the PPD of our model parameters was again performed using emcee. Gaussian priors were set on $f_1$ and $f_2$ using the same spectroscopically derived values as in the CHEOPS fit. Gaussian priors were also set on $h_1$ and $h_2$, using the stellar parameters given in Section 2 and assuming the same offset, but using the TESS passband to interpolate our values. For EBLM J1741+31 a prior on eclipse depth $L$ was again set using the predicted flux ratio of the target, adjusting to $M_G$ magnitudes from Pecaut & Mamajek (2013) due to the different passband of TESS. EBLM J1741+31 required more steps than EBLM J1934–42 to ensure the number of steps in the simulation was more than 50 times longer than the autocorrelation length in each parameter chain. We sampled a chain of 128 walkers each going through 20 480 steps for EBLM J1934–42 and 81 920 steps for EBLM J1741+31, with initial orbital parameters determined by a least-squares fit of the light curves. To allow the walkers to settle into the probability distributions, we performed a burn-in of 2560 and 5120 steps before the sampling for EBLM J1934–42 and EBLM J1741+31, respectively. The parameter values given in Table 4 are the median value of the parameters from the sampled PPD and the standard errors are estimated from the 15.9 per cent and 89.1 per cent percentile-points in the distribution for each parameter. In EBLM J1741+31, similarly to the CHEOPS light curve, there are very strong correlations between $D$, $W$ and $b$ as can be seen in Fig. B4. In EBLM J1934–42, the correlation between these parameters is not as strong. Though there are a small amount of walkers that tend to larger values of $D$ and $b$ as can be seen in Fig. B5, this is a smaller trend than in the CHEOPS light curve. The light-curve fit and residuals are shown in Fig. 2.

3.4 Mass, radius, and effective temperature

To obtain values of companion mass and radius, we made use of the function MASSRADIUS in PYCHEOPS. The M-dwarf mass is determined from the assumed primary mass $M_1$, orbital period $P$, orbital eccentricity $e$, the sine of orbital inclination $\sin(i)$, and the semi-amplitude of the star’s spectroscopic orbit $K$. The M-dwarf radius is determined from the primary star radius $R_1$ from Table 2 and the planet–star radius ratio from the light-curve analysis, $k$. The value of $\log g_1$ in Table 4 is determined directly from $K$ and the parameters of the transit light curve using equations (4) from Southworth, Wheatley & Sams (2007).
The ratio of the eclipse depths is directly related to the surface brightness ratio, i.e. \( F_2/F_1 = L/D \), where \( F_1 \) is the flux per unit area integrated of the observing bandpass for star 2, and similarly for \( F_1 \). The surface brightness is directly related to a star’s effective temperature, surface gravity, and metallicity, using PHOENIX model atmospheres with no alpha-element enhancement (Husser et al. 2013) for both the metallicity, using PHOENIX model atmospheres with no alpha-element enhancement (Husser et al. 2013) for both the

\( a \)Derived parameters based on Gaussian priors shown in Table 3.

The results for CHEOPS J2046+06 show that CHEOPS light curves can be used to measure radii accurate to about 1 per cent and \( T_{\text{eff}} \) accurate to about 2 per cent for the M-dwarf in EBLM systems with well-defined transits. This is sufficient for our main goal of establishing an empirical mass-radius-metallicity relation for very low mass stars. Observations of 24 additional EBLM binaries with well-defined transits with CHEOPS are on-going. The transit model in CHEOPS does not account for surface features on the primary star due to magnetic activity, e.g. dark spots, faculae, or plages. The impact of these features on the parameters derived is dependent on whether they are occulted by the secondary star or not (Czesla et al. 2009; Pont et al. 2013; Oshagh et al. 2013). Dark spots occulted during the transit will produce small peaks in the light curve. If these are not accounted for in the model then the transit depth will be underestimated, leading to an underestimate for the companion radius. The opposite is true for dark spots not occulted by the companion. We checked the TESS and WASP.
Figure 1. Fitted light curve of EBLM J1741+31 (Top), EBLM J1934–42 (Middle), and EBLM J2046+06 (Bottom) in phase intervals around the transit and eclipse events. The observed data corrected for instrumental trends according to the decorrelation coefficients given in Table A1 are shown in cyan. The transit and eclipse models are shown in green. Binned data points with error bars are shown in blue and the fit between binned data points in brown. The residual of the fit is displayed below the fitted curves.
light curves of our targets for variability on time scales of a few days or more due to the combination of rotation and magnetic activity. For all three targets we find that any such variability has an amplitude \( \lesssim 1 \) per cent (\( \lesssim 0.1 \) per cent for EBLM J2046+06). Spots near the poles of these slowly rotating solar-type stars are not expected, so we conclude that magnetic activity has a negligible impact on the parameters we have derived for the M-dwarfs in these systems.

Our results are shown in the context of other mass, radius, and effective temperature measurements for M-dwarfs in Fig. 3. EBLM J1741+31 and EBLM J1934–42 follow the trend for stars with masses \( \lesssim 0.5 M_{\odot} \) to be larger on average by a few percent than predicted by models that do not account for magnetic activity. The radius of EBLM J2046+06, which is our most precise radius measurement, agrees well with the models of Baraffe et al. (2015).

EBLM J1934–42 is a metal-rich star, which may be consistent with the idea that metallicity has an influence on radius inflation (e.g. Berger et al. 2006; Spada et al. 2013; von Boetticher et al. 2019). Not shown in Fig. 3 are the masses and radii for M-dwarfs in EBLM binaries by von Boetticher et al. (2019) and Gill et al. (2019). We do not yet have effective temperature measurements for these M-dwarfs, but the methods we have developed here can be applied to the CHEOPS and TESS light curves for those stars, as well as other EBLM binaries observed by these instruments, to provide a more complete picture for these systems.

5 CONCLUSIONS
In this paper, we have reported the first results of our CHEOPS observing programme on low-mass eclipsing binaries. We find that the very high precision of the photometry from this instrument and the possibility to schedule observations of individual transit and eclipse events are well-matched to our science goal of measuring an empirical mass–radius–metallicity relation for very low-mass stars. We report three M-dwarf radii and two effective temperatures between our three targets contributing to the rather sparse amount of data at the low-mass end of the H–R diagram. Additional observations from our on-going observations with CHEOPS complemented by further analysis of data from the TESS mission will provide precise and accurate mass, radius, and \( T_{\text{eff}} \) measurements for many very low-mass stars of known metallicity and age. Fundamental data of this quality will be essential if we are to find an answer to the long-standing radius inflation problem.
ACKNOWLEDGEMENTS

This study is based, in part, on observations collected at the Observatoire de Haute-Provence (CNRS), France.

CHEOPS is an ESA mission in partnership with Switzerland with important contributions to the payload and the ground segment from Austria, Belgium, France, Germany, Hungary, Italy, Portugal, Spain, Sweden, and the United Kingdom. The CHEOPS Consortium would like to gratefully acknowledge the support received by all the agencies, offices, universities, and industries involved. Their flexibility and willingness to explore new approaches were essential to the success of this mission. This publication makes use of The Data & Analysis Center for Exoplanets (DACE), which is a facility based at the University of Geneva (CH) dedicated to extrasolar planets data visualization, exchange and analysis. DACE is a platform of the Swiss National Centre of Competence in Research (NCCR) PlanetS, federating the Swiss expertise in Exoplanet research. The DACE platform is available at https://dace.unige.ch. We would like to thank the anonymous referee for their timely review of the manuscript. MIS thanks Giovanni Bruno for his comments on the draft of this manuscript. MIS and PFLM are supported by the UK Science and Technology Facilities Council (STFC) grant numbers ST/M001040/1 and ST/T506175/1. This research is supported from the French Programme National de Planétologie (PNP, INSU).
