## Abstract

Microbial fuel cells (MFCs) are comparatively new technique of simultaneously generating electricity from bio-waste while degrading the organic waste. The use of microbes to generate electricity is an uninterrupted process in MFCs since the bacteria replicate and continue to produce power indefinitely as long as there is enough food source to nurture the bacteria. Besides, MFCs have the potential to produce hydrogen for fuel cells, desalinate sea water, and provide sustainable energy sources for remote areas. Factors like type of electrodes used in the cells, partitioning of cells, oxygen complement and configurations are important factors that affect the performance of MFCs. The fabrication of microbial fuel cells of different configurations and the relationship between the factors affecting the efficiency of single chambered (SC-MFCs) and double chambered (DC-MFCs) will be presented. The experimental data on observations made on the effects of these materials on the MFCs characteristics, electricity generation and wastewater treatment have also been included. The main aim of this study is to find out whether a nonconventional inexpensive clay could be used as an ion-exchange medium alternative to the conventional expensive PEM in the fabrication of MFCs. The results obtained on power generation, current density, open circuit voltage, etc., clearly show that PEM-less MFCs can be used as practical devices for sustainable energy generation.

**Keywords:** MFC (microbial fuel cell), current density, power density, SC-MFC (single chambered MFC), DC-MFC (double chambered MFC), OCV (open circuit voltage), COD (chemical oxygen demand)

## 1. Introduction

The production of electricity from waste and renewable biomass using microbes has gained much attention in the recent past [1]. There are three main parts in MFCs [1, 2]. (1) An anode chamber where fuel is oxidized by microorganisms and electron as well as protons are generated. (2) A cathode chamber where electrons and protons are consumed, producing water...
by combining with oxygen. (3) A cation exchange membrane (CEM) which transfers protons from anode chamber to meet with the electrons transferred through external electric circuit from anode chamber to cathode chamber [3–6]. The fuel for the cell is usually domestic or industrial wastewater which contains microorganisms and organic compounds. The reaction for the catabolic activity of the microbes may be summarized as follows:

**Equation 1:**

\[
\text{C}_6\text{H}_{12}\text{O}_6 + 6\text{H}_2\text{O} \rightarrow 6\text{CO}_2 + 24\text{e}^- + 24\text{H}^+ 
\]

**Reduction half reaction:**

\[
24\text{H}^+ + 24\text{e}^- + 6\text{O}_2 \rightarrow 12\text{H}_2\text{O} 
\]

**Overall oxidation/reduction reaction:**

\[
\text{C}_6\text{H}_{12}\text{O}_6 + 6\text{O}_2 \rightarrow 6\text{CO}_2 + 6\text{H}_2\text{O} 
\]

Thus there are two halves of the microbial fuel cell: the aerobic chamber having positively charged electrode with oxygen in abundant, and the anaerobic chamber having negatively charged electrodes. The semi-permeable membrane separate the two chambers allows only hydrogen ions (H\(^+\)) and keeps oxygen out of the anaerobic chamber [7].

The main challenges in constructing microbial fuel cells (MFCs) are the identification of materials and architectures that maximize power generation and efficiency, also minimizing the cost of fabrication. Various researchers have tried to use different materials and various architectures for the electrode and membranes. In order to get better performance, a broad range of techniques have also been used [8]; which include “doping” of the anode, varying the electrodes and the use of various types of cathode substrate.

### 2. Advantages of PEM-less microbial fuel cells over PEM architecture

As we know, the PEM key function is to keep the liquid contents of each chamber separate while still allowing protons to pass between chambers to be utilized in the cathode with the produced electrons. Although proton exchange membranes are often used, Logan [10] has reported that Cation exchange membranes (CEM) work in a similar way but more cost effective than PEM, and sometimes structurally stronger. Both PEM and CEM support in reducing oxygen diffusion in the anode chamber of the cell. However, after using PEM for some of MFCs we have realized that PEM is quite expensive and very delicate to work with. It cannot be reused and also difficult to adapt to desired shapes.

We therefore started searching for other alternatives to replace the most costly and delicate PEM. In the process of this search we came across a local clay mixed with kaolin and bentonite and subsequently fired appropriately achieved the desired results of producing open circuit voltage (OCV) of up to 1.5 volts. This clay system is quite unique, robust, potable, cheap, easy
to acquire locally and can be shaped as desired. It can also be molded to large cells. Even though some cheaper alternatives have been used by many researchers, the use of rigid cation exchange materials such as the clay used in the fabrication of some of MFCs in this research have not been given much attention that is most cost effective and easy to give any desired shape.

3. Section A

This section includes the fabrication, operation and results of three different types of Microbial Fuel Cells (MFCs).

3.1. Single-chambered (SC-MFC) PEM microbial fuel cell

In order to find the effect of chemical oxygen demand (COD) on the open circuit voltage (OCV), Power production and coulombic efficiency single–chambered Microbial Fuel Cells (MFCs) have been fabricated. Three different MFCs of similar design have been fabricated using carbon paper doped with platinum as cathode and graphite as anode separated by Proton Exchange Membrane (PEM) and the effect of COD level on Open Circuit Voltage (OCV), power production and Coulombic efficiency have been studied.

3.2. Double-chambered (DC-MFC) PEM microbial fuel cell

A variety of substrates have been explored relative to the anode substrate which takes the form of any wastewater with some amount of COD. Several modification methods have been developed to improve power generation at the anode level, but the cathode system and configuration have also been a challenge in most researches. The choice of cathode substrate is one of the greatest challenges in fabricating MFCs. A DC-MFC with H\textsubscript{2}O\textsubscript{2} cathode has been fabricated and compared with SC-MFC.

3.3. Membrane less microbial fuel cell

In this case, a number of clay mixtures have been used as ion-exchange partition replacing Proton Exchange Membrane (PEM) in designing the MFC and observations have been made on the effects of these materials on the MFCs characteristics; electricity generation and wastewater treatment. The performances of the cells have been then compared in terms of wastewater treatment, power generation and coulombic efficiency.

3.4. Methodology

3.4.1. Single-chambered (SC-MFC) PEM microbial fuel cell

3.4.1.1. Preparation of PEM

Nafion 117 of area 12.6 cm\textsuperscript{2} was taken through the normal cleaning process [distilled water → 3% hydrogen peroxide → dilute sulfuric acid → distilled water].
3.4.1.2. Fabrication of MFCs

Necessary steps for the fabrication of MFCs:

- 2 Perspex slabs were cut, shaped and dilled for each cell.
- Carbon paper doped with platinum was cut and shaped.
- Copper conductor was cut and shaped.
- Preparation of Graphite electrode.
- A plastic container of 2 liters capacity served as the anodic chamber. The anode chamber contains the wastewater and the graphite electrode. The carbon paper tightens onto the PEM served as the cathode.

3.4.1.3. Types of wastewater for MFCs

Following three types of wastewater of different COD and pH from GGBL (Kumasi, Ghana) were used as Fuel for these cells. The characteristics of the wastewater are listed in Table 1:

| Wastewater     | COD (mg/L) | pH  |
|----------------|------------|-----|
| Influent       | 3790.0     | 11.18 |
| Anaerobic      | 748.0      | 6.80  |
| Balance        | 4330.0     | 6.01  |

Table 1. Type of wastewater used.

3.4.1.4. Operation

The cells were kept at 25°C (±0.5°C). The anode was immersed in the wastewater such that the copper conductor did not touch the water in order to avoid corrosion. The anode chamber was sealed to maintain anaerobic system throughout the experiment. OCV readings were taken for 35 days with the CR10X datalogger which stores the differential voltage every 1 min. A multimeter (Peak Tech 2010DMM) was used in the reading of the load voltage and the current through a resistance box ranging from 0 to 10,000 Ω.

3.4.1.5. Results

The experiment was operational for 35 days. A constant increment of OCV was observed from day one of the operation of MFCs until it got to their peak values of OCV. These values were maintained for about 10 days. Also their pH and COD values at the end experiment are given in Tables 2 and 3. The experiments were performed with the wastewater as collected in order to check the viability of the cells without adding inoculants and other chemicals (Figure 1).
3.4.2. Double-chambered (DC-MFC) PEM microbial fuel cell

3.4.2.1. Architecture

We fabricated the DC-MFC with the porous pot (5 mm thick) containing the anodic substrate immersed into the copper can containing the \( \text{H}_2\text{O}_2 \) catholyte substrate (Figure 2), both having a working volume of 300 mL in each compartment. The anode electrode is a zinc rod having an outer diameter of 1.2 cm and a geometric surface area of 38.8 cm\(^2\) and the cathode is the copper can housing the porous pot (this is similar to a Daniel cell). The pot acts as an ion exchange partition. We connected the anode or the zinc rod to the cathode compartment through a copper wire and external resistor of 1000 Ω. The assumption is that the porous pot separation permit only cation transport to the oxidation substrate, as done earlier [9]. The initial pHs in the wastewaters were measured and are shown in Table 2.

| Wastewater | Starting COD | Ending COD | Starting pH | Ending pH |
|------------|--------------|------------|-------------|-----------|
| Influent   | 3790.0       | 133        | 11.18       | 8.3       |
| Anaerobic  | 748.0        | 59         | 6.8         | 8.9       |
| Balance    | 4330.0       | 267        | 6.01        | 8.6       |

Table 2. pH values obtained.

| Day  | pH  | Temp. °C | COD (mg/L) | ΔCOD | ACOD |
|------|-----|----------|------------|------|------|
| 1    | 5.9 | 26       | 7700       | —    | —    |
| 2    | 6.1 | 28       | —          | —    | —    |
| 3    | 6.1 | 26       | —          | —    | —    |
| 4    | 6.2 | 27       | —          | —    | —    |
| 5    | 6.4 | 27       | —          | —    | —    |
| 6    | 6.6 | 28       | —          | —    | —    |
| 7    | 6.7 | 28       | —          | —    | —    |
| 8    | 6.9 | 27       | —          | —    | 1650 |

Table 3. Change in pH of the wastewater with activities of microbes through the days.

3.4.2. Double-chambered (DC-MFC) PEM microbial fuel cell

3.4.2.1. Architecture

We fabricated the DC-MFC with the porous pot (5 mm thick) containing the anodic substrate immersed into the copper can containing the \( \text{H}_2\text{O}_2 \) catholyte substrate (Figure 2), both having a working volume of 300 mL in each compartment. The anode electrode is a zinc rod having an outer diameter of 1.2 cm and a geometric surface area of 38.8 cm\(^2\) and the cathode is the copper can housing the porous pot (this is similar to a Daniel cell). The pot acts as an ion exchange partition. We connected the anode or the zinc rod to the cathode compartment through a copper wire and external resistor of 1000 Ω. The assumption is that the porous pot separation permit only cation transport to the oxidation substrate, as done earlier [9]. The initial pHs in the wastewaters were measured and are shown in Table 2.
the anode and cathode chambers were 5.9 and 6.8 respectively. The setup was then connected to a Datalogger (Campbell Scientific Datalogger CR10X) to store potential difference across the load at 1 min interval. The cell was placed in the laboratory condition of ambient temperature between 26 and 29°C and at 1 atm.

3.4.2.2. Results

Table 4 was experimental calculations in terms of current densities and power densities for comparing the normalization. According to Ref. [10] the above parameters sufficiently describe how efficiently a power is generated by a given system architecture. It can be assumed that protons generated from the bacteria metabolism are conducted through the porous pot to balance the charge in the cathode compartment. In this regard, the operation surface area of the pot may have favor anion-cation coupling and thus accounts for the high OCV observed.

3.4.3. Membrane less microbial fuel cell

3.4.3.1. Materials and methodology

Kaolin and Zeolite were used for the ion exchange media in the earlier experiments which were in the process of publication. In this project we designed two pots or chambers which were custom-made cylinders using Mfensi clay. The capacities of the pots are 1.7 and

| Surface area of rod | Inner surface area of pot | Volume of anode substrate |
|---------------------|--------------------------|---------------------------|
| 38.8 cm$^2$         | 219.44 cm$^2$            | 300 mL                    |
| Max. current density| 311 mA/m$^2$             | 55 mA/m$^2$               |
|                     | 4020 mA/m$^2$            |                           |
| Max. power density  | 375 mW/m$^2$             | 6628 mW/m$^2$             |
|                     | 4848 mW/m$^2$            |                           |

Table 4. Densities as normalized by the measured parameters.
1 L. Mfensi clay is commonly used in Ghana for drinking water pots. Its porosity ranging from 5 to 25% satisfies a process that cools the content by seeping and evaporation system. That is, part of the content water soaks the pot to the outer part; the outer part then dries gradually extracting the heat from the inner content. The result is that the inner content becomes cooler than the surrounding depending on the rate of evaporation/drying of the outer part. Mfensi clay is also known to have negative charges. The thickness is 1.0 cm and the apparent porosity as measured is 14.3%. We feel these parameters passed for ion exchange to take place. The cells were fed with 1.40 and 0.80 L wastewater respectively from GGBL (Kumasi, Ghana), with initial COD of 4385 mg/L in the anode pots and 40% \( \text{H}_2\text{O}_2 \) surrounding the pots.

### 3.4.3.2. Results

There are two aspects this experiment sort to compare; 1) to check whether this type of clay can exchange ions and serves as anodic pot; 2) to verify if the size of pot (or operation surface area) affects the amount of power produced.

#### 3.4.3.3. Effect of pot size

As observed through the polarization measurements, the smaller pot performed better as shown in Figures 3 and 4. (Pot 1—1.7 L, Pot 2—1.0 L).

Pot 2 yielded a higher potential difference than the pot 1 (which contained more substrate in terms of volume). Same applied to the power densities where the peak occurred at 6429 and 4750 mW/m² respectively.

As shown in Figure 5 the polarization curves depict the activation region and the ohmic region (actual performance region), but the concentration region not that clear.

![Figure 3. Variation of potential drop with external load.](http://dx.doi.org/10.5772/intechopen.71479)
3.4.4. Determination of internal resistance of an MFC

In Figure 5 the peaks occurred at 0.828 mW/m² and 1.53 mW/m² for pot 1 and 2 respectively. These values correspond to 330 Ω internal resistance; same for both cells having similar substrate and similar graphite electrodes. The higher OCV value confirms that an MFC that is connected with an external resistance comparable to its internal resistance will produce maximum power [9, 11].
3.4.4.1. Zeolite cells

20% Zeolite was added to Koalin (80%) and molded to a slab of 8 × 8 × 1 cm. This was then fired at the temperature of 3000°C.

3.4.4.2. Results

All the cells were connected to a Datalogger (CR10X) and were observed for 30 days. The open circuit voltage (OCV) for all the cells were recorded every minute and stored for few minutes. Data were then collected via computer interface. Table 5 shows sample data as collected in excel format.

| ID | Yr | ProgReg | Time | Pot 1 OCV/mV | Pot 2 OCV/mV | Pot—Cu OCV/mV | Pot—Tin OCV/mV | Zeolite OCV/mV |

Table 5. Sample data as stored by the Datalogger.
Both cells were fed with same wastewater of COD = 4385 mg/L and same diluted H$_2$O$_2$. It was found that the OCVs generated by the Cu-Can/porous-pot cell was higher as compared with the zeolite cell, i.e., 1337 and −17 mV respectively. We suspected the zeolite by its property absorbs the ions and release when it can no longer contain it and thus accounts for the negative OCV from the start. Load of 100 Ω was then connected across the terminals of the zeolite cell and 1000 Ω was connected across the pot cell. The recorded voltages now become the potential drop for both DC-MFCs. The readings per minutes were averaged to hours of reading so as to reduce volume of data that can be handled. The result is plotted in Figure 6.

It was observed that at the stationary phase microbial growth rate is balanced by microbial death rate as a result of paucity of food and nutrients, as well as the presence of waste metabolic products. Consequently, a stationary population is achieved, but too early or may be due to the flow of current across the bridge. Death phase stage sees to a greater increase in death rate, as compared to growth rate, resulting in a sharp decrease in the number of microbes over the days.

3.4.5. Polarizations

For similar characterization, each cell was subjected to variable loads ranging from 100 to 15,000 Ω and the voltage drop values recorded as given in Table 6. This is required to examine the extent to which the cells could be used to power the devices. Both cells were normalized by their operational surface areas; for porous pot the total surface area containing the anodic substrate was 219.4 cm$^2$ and that for zeolite slab was 16.0 cm$^2$ (Figure 7).

Figure 6. Zeolite and porous pot MFCs: OCV and Pd time variation curves.
It has been found that the Balance wastewater produced power most significantly than the other two. It has been observed that the current generation of the cells increased for a higher COD and lower pH. The removal of COD of observed to be highest for the cell which produces higher current. The COD for Balance dropped from 4386 to 267 mg/L for the 36 days of running (Tables 7 and 8).

Summary of other Generated Parameters:

### Table 6. Cells characterization data.

| Resistance | Current | Cur-Den | Pd | Pow-Den | Current | Cur-Den | Pd | Pow-Den |

Table 8. Measured MFCs characteristics of the two pots.
The factors that affect the cathode and anode potentials were investigated. Compared with other membrane types, cation exchange partition, clay anodic container and aluminum cathode container assembly yielded such performance. This system might be useful in applications of MFC type at a very low cost. Mfensi clay is said to have negative charges which might be responsible for negative OCV. This approach represents a potential solution for simultaneous electricity production and removal of COD and thus offers a technological tool both for sustainable energy generation and for economic viability.

Both, double chamber membrane-less-microbial-fuel-cells (MLMFCs) were found to give COD reduction greater than 88%, with maximum power production 20.48 mW/m² as normalized with the anodic substrate container surface area. It was expected to generate enough power to light a LED through only one cell so as to be able to power low voltage circuits or devices. However, efforts are being made to improve the structures of Zeolite DC-MFC for better performance.

4. Section B

4.1. Effect of COD and H₂O₂ concentration on double chamber MFC (DC-MFC)

In the present section an attempt has been made to investigate the effect of hydrogen peroxide (H₂O₂) and COD on the performance of DC-MFCs. It has been found that 80% H₂O₂ or a mixture of 1:4 exhibited higher power generation while 20–60% concentration have no effect. This shows that H₂O₂ can be used as oxidizing agent between the concentrations of 70–90%. The values of power densities of the order 24.56 W/m² for Balance substrate (7562 mg/L COD) for 80% H₂O₂ confirms the effect of CODs on the performance of DC-MFC.

The results of this study indicate that the efficiency in DC-MFCs can effectively be increased by varying the concentration of H₂O₂ as cathodic substance. Specifically, the investigation shows that this paper supports the earlier result by [9] of the use of hydrogen peroxide as cathode substrate. Upon investigation of different catholyte concentrations, dilution of H₂O₂ at a certain level must be necessary to achieve high efficiency and power generation.

4.2. Fabrication of DC-MFC

The MFC chambers were fabricated using plastic containers of two equal volume of 1.8 L each. These anode and cathode chambers were separated by proton exchange membrane (PEM—Nafion 117) [9] as shown in Figure 8.

Two different kinds of waste water obtained from the Guinness Ghana Brewery Limited (GGBL—Kumasi) were used in the anode chambers, one with COD—1273 mg/L and the other with COD—7562 mg/L. the cathode chambers were filled with H₂O₂ mixed liquid. Plain graphite rods of surface area 86.7 cm² were used as cathode and anode; as the surface area of anode does not affect power production [10]. The voltage and current were measured with a Digital multimeter (Peak Tech® 2010 DMM).open circuit voltage E was obtained and stored using a data acquisition system (Campbell Scientific Ltd. Datalogger—CR10X).
In systems that contain a membrane separating the two electrode chambers, it is possible to normalize power based on the membrane projected surface area;

Current Density normalized by PEM area = \( \frac{E}{A_{\text{PEM}}} \)

Power density as normalized with PEM area = \( \frac{E^2}{R A_{\text{PEM}}} \)

Power density as normalized with volume of anode chamber = \( \frac{E^2}{R V_{\text{an}}} \)

Where \( E \) is load voltage, \( R \) is load resistance, \( A_{\text{PEM}} \) is active PEM area and \( V_{\text{an}} \) is volume of anode chamber.

4.3. Results

The open circuit voltage as against concentration of \( \text{H}_2\text{O}_2 \) at the anode chamber is shown in Figure 9. Whereas the open circuit voltage in relation with time has been shown in Figure 10. Also the variation of power with current density for various concentrations of \( \text{H}_2\text{O}_2 \) is shown in Figure 12.

The drops and the ramps were observed to occur in the nights where the temperature dropped from 28°C to between 27°C and 25°C. This temperature effect may not be for the peroxide, but for the biological substrate.

Polarization curves were obtained by varying external resistances from 100 to 10,000 \( \Omega \) (Figure 11).

As may be seen in the above Figure 9, the 80% concentration at the cathode exhibited a significantly high polarization than expected. It should also be observed that the addition of 20% water showed about 80% increase in voltage over the pure peroxide (100%). The fact that the other concentrations in the cathode chamber performed so poorly in comparison to the 80% concentration is evidence that potential difference may be dependent on the number of ions exchanged between anode and cathode chambers. Non-diluted hydrogen
peroxide (100%) in the experiment washed the surface of the cathode clean. This may be due to the high reactivity of $\text{H}_2\text{O}_2$. This also shows that $\text{H}_2\text{O}_2$ is an oxidation agent between 75–90% concentration.

Figure 9. OCV versus hydrogen peroxide concentration.

Figure 10. Performance comparison in relation to open circuit voltages plotted as a function of time for varying concentration.
Figure 11. Performance comparison in relation to hydrogen peroxide (6% w/v with stabilizer) concentration.

Figure 12. Variation of power with current density for various concentrations of H$_2$O$_2$. 
Similar characteristics were observed for power versus current density relationship. Maximum power density as normalized with PEM area is 24,564 mW/m², which is equivalent to 17.2 mW/L as normalized by substrate volume.

4.4. Effect of CODs and H₂O₂ concentration on power density

As H₂O₂ concentration is crucial in this experiment as the CODs of the substrates, though the percentage dilution has significant impact on the performance of the two systems. Moderately, the earlier result indicated that the power density actually depends on the COD of the anodic substrate. As shown in Figure 12 the OCVs were not far apart and thus compare favorably, but this could not be said about their power densities. From 20 h on more ions may have been released as bio-activity increases. The peaks of their power densities were far apart and would have been dependent on the CODs of the two systems as exhibited in Figure 13.

The OCV may be similar, but as current strictly depends on the number of useful electric charges present in the system are responsible of bio-electrochemical reaction; the reason would be probable.

![Figure 13. Comparative state of the two similar MFCs.](http://dx.doi.org/10.5772/intechopen.71479)
5. Section C

5.1. Multi-chamber microbial fuel cells (MFCs) with clay as ion exchange partition

This section includes the performance of multi-chambered MFCs. Performance of each micro cell in the system was observed to be significant in terms of their yields as could be in standalone single cell. Each adjacent cell tends to supplement the other so that series configuration is not possible in the same multi-system. In parallel configuration, all anode terminals connected as one and all cathode terminals connected together, resulting in higher current as shown in Figure 14. This higher power can therefore perform for longer period when connected to a load. Few experimental uses attested to such performances.

5.1.1. Materials and methodology

The clay material was obtained from Mfensi, a town near Kumasi—Ghana. As in Table 9 was the constituent of the clay as used in the earth wares sold in the market.

The varying chambers were molded and fired at the Department of Ceramics, KNUST. The chambers were in 2, 4, 6, and 9 sets. As in Figure 14 a chamber is $3.8 \times 3.8 \times 9$ cm (approx. $130$ cm$^3$ in volume) and 0.6 cm thick. Porosity was measured to be 14%. The outer part of each set of pot was coated to prevent the liquid seeping out.

5.1.2. Wastewater used in MFCs

Wastewater from the Guinness Ghana Brewery Limited (GGBL, Kumasi) has being our favorite for anode substrate, primarily because of its known source and safety measures attached to its disposal. Besides, it is suitable for electricity generation in MFCs due to the food-derived nature of the organic matter. Good results were obtained in earlier studies with this wastewater.

| Element | %     | Element | %     |
|---------|-------|---------|-------|
| Na$_2$O | 6.15  | K$_2$O  | 1.66  |
| MgO     | 1.28  | CaO     | 0.54  |
| Al$_2$O$_3$ | 13.82 | TiO$_2$ | 0.04  |
| SiO$_2$ | 65.26 | MnO     | 0.07  |
| P$_2$O$_5$ | 0.23 | FeO$_3$ | 0.83  |
| SO$_3$  | 0.10  | LOI     | 10.00 |
| Cl      | 0.02  | Total   | 100   |

Table 9. Composition of Mfensi clay from geological survey department (Ghana) X-ray fluorescence laboratory results.
ter with varying CODs [9, 12, 13]. Each cell was fed with wastewater of COD equals to 6340 gm/L and 80% concentration of H\textsubscript{2}O\textsubscript{2} alternatively. 80% concentrated H\textsubscript{2}O\textsubscript{2} was done earlier to ascertain the veracity of suitable dilution for higher performance [13].

5.1.3. Choice of electrodes

Most of the publications on suitable electrodes [10, 14] have laid emphasis on carbon and its variance, but these experiments continually use zinc rods and copper plates for good results. In the present work, zinc plates of surface area 24 cm\textsuperscript{2} each were inserted in the wastewater and copper rod of same surface area placed in the H\textsubscript{2}O\textsubscript{2} respectively making each adjacent pot forming a cell (Figure 15).

![Figure 14. Comparative power densities versus current densities of the two MFCs.](http://dx.doi.org/10.5772/intechopen.71479)

![Figure 15. Designed and fabricated Mfensi clay chambers; anode/cathode chamber applied to all cells.](http://dx.doi.org/10.5772/intechopen.71479)
5.1.4. Measurements

Each cell was connected to Datalogger (Campbell Sci CR10X), open circuit voltage (OCV) and potential drop across 1 K load were recorded per minute for 35 days. Ambient temperature varied over the period between 24°C and 25°C.

5.2. Parallel connection

4, 6 and 9 combinations were connected in parallel (Figure 16) and to the Datalogger. That is, zinc plates in each anode pot were connected together and copper plates were also connected together as one terminal.

5.3. Series connection

Series connection in the multi system appeared isolated and as in Figure 16b each cell was connected to a load and thus tend worked independently. Such single cell measurement was plotted in Figures 17 and 18.

5.3.1. Results

There were two aspects of these experiments sort to compare; 1) measure the performance of single cell in the multi MFC system; 2) performance of total multi cell as a single cell. Although all the cells were co-joint with each other as the partition between them act as ion-exchange medium. Each adjacent pot combination in the alternative forms a cell. The cells were also taken through the polarization measurements using resistors of 100–15,000 Ω. Voltage drops were recorded through PeakTech 2010DMM Multimeter.

First portion of Figure 17 (A) on the curves presented OCVs recorded by the Datalogger without load. When the loads were connected there were sharp drops in line with ohm’s law of electric circuit calculation [15]. Some of the cells continually dip with hours of operation while others maintain constant voltages (B). 9 and 6 chambered cells configured into parallel cells each respectively, were the top 2 of higher operation voltages, meaning these can be used for longer operation period.

![Figure 16. (a) Parallel cell configuration (9 chambered cell); (b) Series cell configuration.](image-url)
Current density was calculated based on the surface area of the anode electrode ($I_D = \frac{P_d}{R_{an}}$), and Power density was then calculated using $P = I_D E$ (where $I_D$ is the current density and $E$ the voltage drop).

*Figure 17.* Voltage recorded for the first 5 days.

*Figure 18.* Voltage drop across varying resistors against current density.
It was observed that OCV did not follow a pattern (Figure 18). The fourth cell from the 9 chambered cell had the highest OCV of 1414 mV which was probably due to the fact that this particular cell had two anodes and one cathode.

From both polarization and power curves for 4/2Cell show the highest yield, compared to 4/1Cell. Although the OCV for 9/4Cell was highest it was not consistent with ohmic portion of characteristic curves of Figures 18 and 19. These curves show how well the cells maintain voltages as a function of the current produced. Resistive effects in fuel cells reduce the

![Figure 19. Histogram resulting from Table 10.](image1)

![Figure 20. Power density verse current density comparing individual cell in multi MFC system.](image2)
efficiency of the cell by dispelling power in the partitions and substrate resistances. This
effect is also observed due to the insulation of the anode electrode. The voltage generated
here is far more complicated to understand or predict, and as usual the inference can be
deduced from the total result. Almost all the individual cells have their internal resistance
$R_{\text{int}} = 330 \, \Omega$, and [10, 15, 16] we see that the maximum power resulted at a point where
$R_{\text{int}} = R_{\text{ext}}$, then $P_{\text{max}} = E_{\text{emf}} / 4R_{\text{int}}$ [17].

The parameter that must have caused the variation in nature of the histogram with
regards to 4/2Cell might be due to the partition characteristic between anode/cathode of
the cell, with all other factors been the same; i.e. substrates, anode, cathode and ambient
conditions.

The maximum power as shown in Figure 21 was 41.25 mW/cm² for 9 chambered cells. The
activation losses and ohmic portions of the polarization curves were more pronounced in both
Figures 17 and 20. The concentration polarization drops were overcome within the range of
load/resistors (100–15,000 Ω) used for the measurements. Concentration losses are most impor-
tant loss parameters to be overcome for optimum design of the MFC architecture. These losses
were said to arise from resistance of ion conduction due to the substrates and the membrane or
partition between anode and cathode, the flow of electrons through the electrodes to the contact
load points [10]. Our choice of clay partition could have accounted for reduction in concentra-
tion losses and also ensuring good contacts in the circuit, and the source of anode substrate that
enhanced solution conductivity.

Figure 21. Polarization and power density curves for parallel combination multi MFC system.
6. Section D

6.1. Mfensi clay as ion-exchange-partition in double chamber microbial fuel cells (DC-MFCs)

This section includes the development of a low cost double chambered microbial fuel cells (DC-MFCs) for power generation as well as for wastewater treatment simultaneously. These fuel cells were fabricated using a locally available Mfensi clay as an ion-exchange-partition. These cells also used pot-electrode combination that is: (1) pot-graphite/graphite combination and (2) pot-zinc/copper combination. Both MFCs were connected to a Campbell Datalogger CR10X to measure and store initial open circuit voltages (OCV) as well as potential drops across 1000 Ω resistor for 30 days. Experimental results showed maximum power densities of 118 and 79 mW/m\(^2\) for the Pot-zinc/copper pair electrode and Pot-graphite/graphite pair electrode respectively.

6.2. Materials and architecture of DC-MFCs

The materials used for this work includes Mfensi clay from the Atwima Nwabiagya District in Ashanti Region of Ghana, The clay is known to have negative charges. Two cylindrical chambers (Figure 22) of capacities of 1.7 and 1 L and thickness of 1 cm were fabricated...
from the clay and fired at a temperature of 1050°C in the Department of Ceramics – College of Arts and Social Sciences, KNUST. The apparent porosity of the cylinders as measured was 14.3%. Figure 23 shows an MFC assembly consisting of an improvised cathode which was an Aluminum cooking utensil housing the cylindrical chamber and also containing 40% diluted hydrogen peroxide (H₂O₂). The ion-exchange partition houses the anodic substrate. The two cells under investigation were fed with 1.40 and 0.80 L wastewater respectively from Guinness Ghana Breweries Ltd. (GGBL- Kumasi, Ghana), which had an initial COD of 4385 mg/L.

6.3. Results and discussion

Figure 24 shows the variation in potential drop (OCV) with time for zinc/copper and graphite/graphite electrode pairs. Pot-graphite/graphite pair yielded contrary results although same substrates were used. The results obtained for this electrode pair (the lower curve of the plot) shows a gradual rise of the initial OCV of −300 mV to almost 0 V after which a gradual fall was observed over the time period. The negative result of pot-graphite/graphite pair was thought to be the effect of negatively charged of Mfensi clay that tend to neutralize the incoming positively charged ions from the anode.

The polarization curves as well as plots of power densities versus current densities for cells loaded with incremental load of 100–1500 Ω have been depicted in Figures 25–27. Figure 25 shows that pot-zinc/copper pair produced higher values in relation to the applied external
6.4. Determination of internal resistance of the cells

The internal resistance is one of the major characteristics of a MFC, in accordance with the theorem of maximum power delivered by an electromotive force. An MFC connected with an external resistance equals to its internal resistance will give a maximum power output [10, 11]. From Figure 27 the peaks occurred at 118 and 79 mW/m² for zinc/copper and graphite/graphite systems respectively. The alternative to finding internal resistance was calculated from the slope of Figure 26. The peak value corresponds to 200 Ω internal
resistance for zinc/copper system and 556 Ω graphite/graphite. The internal resistance however seems to be high for graphite/graphite system, as can be anticipated using the polarization curve method (Table 11).

The unconventional inexpensive Mfensi clay ion-exchange medium used for the study seems to be a viable alternative to the conventional expensive PEM. It was observed that a porosity of 14.3% may facilitate the flow of liquid in both directions though. We believe it holds the future for improvements in MFC performance. This approach represents a potential solution for simultaneous electricity production and removal of COD and thus offers a technological tool for sustainable energy generation.
I would like to thank Prof. K. Singh, the co-author of most of the research papers on MFCs for assisting in the preparation of this chapter. I would also like to thank the Department of Physics for providing necessary facilities for the work. I sincerely thank the management of Guinness Ghana Breweries Limited (GGBL, Kumasi) and staffs for the supply of wastewater and their help with the analytical measurements of COD for the entire project.
