Abstract. Dimethyl ether (DME) can be used as a replacement for diesel fuel in transportation. The catalytic effectiveness of bifunctional catalysts for DME one-stage synthesis from carbon monoxide and hydrogen was estimated in the paper. Bifunctional catalysts CuZnAl/HZSM-5, CuZnAlCr/HZSM-5, and CuZnAlZrHZSM-5 were obtained by physical mixing of CuZnAl(Cr/Zr)–Ox and HZSM-5 components and were characterized by BET, X-ray diffraction, and temperature-programmed surface reaction methods. Based on the TPSR results, the mechanism of the interaction of methanol and DME with the surface of the bifunctional catalyst was studied. It was found that the temperature range of the greatest catalytic activity was 240–260 °C.

1 Introduction

Research on alternative fuels has mainly started due to ecological and economic considerations. The synthesis and application of synthesized dimethyl ether (DME) are relevant to developing alternative energy [1]. DME is widely used, environmentally friendly, and ultra-pure product substituting for automotive and household fuel. There are two methods of producing DME as a two-step one consisting of methanol synthesis from syngas followed by dehydration, and one-step method involving synthesizing DME directly from syngas attracting the attention of researchers and manufactures in many countries [2]. The development of bifunctional catalysts (BC) for the direct synthesis of DME has received great attention in the literature.

The synthesis of DME involves the following reactions:

Methanol synthesis:
1. CO + 2H₂ ⇌ CH₃OH
2. CO₂ + 3H₂ ⇌ CH₃OH + H₂O

Methanol dehydration to DME:
3. 2CH₃OH ⇌ CH₂OCH₂ + H₂O
4. CO₂ + H₂ ⇌ CO + H₂O.

The most widely studied catalysts for the direct synthesis of DME use CuO-ZnO-Al₂O₃ as function methanol formation (1 and 2 reactions). Research has been focused on increasing their stability, improving the dispersion of Cu and incorporating different metallic promoters (Cr, Fe, Mg, Mn, and Zr oxides) [3-7]. For the function methanol dehydration (3 reaction), catalysts of different porous structure are used (γ-Al₂O₃, silica-alumina, HZSM-5, NaHZSM-5, mordenite, HY, ferrierite, HMCM-22, SAPOs, and ZrO₂) [8-12]. Conventionally, BC are used, whose particles are prepared by physical mixture of the methanol formation and dehydration catalysts, and subsequent pelletizing [13].

The reactions mechanisms which occurring on the catalysts surface during synthesis of methanol and its dehydration are examined in the literature. However, the processes on the surface of the BC with parallel reactions of formation and dehydration of methanol have not been fully considered [13-17].

2 Materials and methods

In our work we synthesized three types of BC by physical mixture adding methanol synthesis catalyst (CuZnAl-Ox (CZA), CuZnAlCr-O (CZAC), and CuZnAlZr-Ox (CZAZ) to methanol dehydration catalyst (HZSM-5). BCInitial powders were individually grounded in an agate mortar for 15 min followed by pelleting of the solid mixture. Chemicals as CZA, CZAC, and CZAZ were prepared by co-precipitation in aqueous solutions containing appropriate metal nitrates in constant pH and temperature as described in [18]. A ZSM-5 zeolite (Institute of Petroleum Chemistry of the Siberian Branch of the RAS) in its protonic form was used as methanol dehydration catalyst as described in previous studies [11, 12]. The selection of the conditions

Corresponding author: kurzina99@mail.ru
for carrying out the reaction was based on theoretical calculations [19].

Porous structure (pore volume, V, and size, d,) and specific surface area (S_{BET}) of the catalysts were determined from the data of nitrogen adsorption isotherms observed at -196 °C, using the automatic TriStar II 3020 analyzer of Micromeritics (USA). The value of the specific surface area was determined by the Brunauer–Emmett–Teller (BET) theory method from nitrogen adsorption X-ray phase analysis was performed with a Rigaku MiniFlex 600 using CuKα-radiation with a monochromator. The size of the ordered domains (r) was evaluated using the Scherer method.

The catalytic effectiveness, estimated as yield of DME, BC was tested using a high-pressure fixed-bed reactor at pressure of 3 MPa, temperature of 260 °C, weight ratio ‘H\(_2\)/CO’ = ‘2:1’, and weight hour space velocity of 576 h\(^{-1}\). Gaseous hydrogen and carbon monoxide were used as components of the initial reaction mixture. A catalyst with a particle size in the range of 0.5–1.0 mm was used, and 5.0 cm\(^3\) of the samples were loaded into the reactor. Gas chromatographic analysis of the product was carried out on a gas chromatograph Crystal 5000.2 [20].

Temperature-programmed surface reaction (TPSR) was used to study the interaction of methanol and DME with the surface of the catalysts. TPSR was carried out using a chemisorption analyzer Chemisorb 2750 (Micromeritics, USA) combined with the quadrupole mass spectrometer UGA-300 (Stanford Research System, USA). Prior to the experiment, the sample was treated with a hydrogen-containing gas stream (10% H\(_2\) in Ar) at 350 °C. Adsorption of DME was carried out at 100 °C for 30 min in adsorbate gas stream of at the rate of 20 ml/min. Methanol (99.9 purity, Acros Organics) was injected with a microsyringe through an evaporator at 100 °C into a stream of an inert carrier gas (He). After adsorption, the sample was left in the carrier gas stream for 30 min to remove the residues of the adsorbate. The thermo-desorption experiment with a mass spectrometric analysis of the desorption products was carried out in a stream of He gas at the rate of 20 ml/min and a linear heating rate of 10 °/min from 100 to 500 °C.

3 Results and discussion

The highest yield of DME (13%) was demonstrated by the use of CZA/HZSM-5 catalyst. However, the sample modified by chromium having less DME yield (11%) gave less content of by-products. For comparison, at 260 °C, the DME yield was 13, 11, and 10% for CZA/HZSM-5, CZAC/HZSM-5, and CZAZ/HZSM-5, respectively. The main by-product of the reaction was carbon dioxide (Table 1).

| Sample       | CO conversion, % | DME yield, % | CO\(_2\) yield, % | CH\(_4\) yield, % |
|--------------|-----------------|--------------|-------------------|------------------|
| CZA/HZSM-5   | 84              | 13           | 36                | 2                |
| CZAC/HZSM-5  | 81              | 11           | 28                | 1                |
| CZAZ/HZSM-5  | 85              | 10           | 28                | 2                |

After the catalytic process, the diffraction patterns of the samples showed phase reflexes in more crystallized state. The XRD showed intense peaks in the region 2θ = 10–30° corresponding to the presence of zeolite in the catalyst. When the catalyst reacted with the reactive atmosphere, copper oxides were reduced to the metallic...
state, which was confirmed by XRD data and accompanied by a decrease in the surface area of the samples shown in Table 1. The value of the size of the ordered domains of the copper particles in the BC after catalysis was close to ~13 nm, while for the catalysts in synthesis of methanol CZA, CZAC, and CZAZ, these values were 17.2, 13.6, and 15.1 nm, respectively.

Table 2. Structural characteristics of catalysts for the DME synthesis before and after catalysis.

| Catalyst       | S, m²/g | V, cm³/g | d, nm | rCu, nm |
|----------------|--------|----------|-------|---------|
| CZA/HZSM-5     |        |          |       |         |
| before catalysis | 121    | 0.2      | 9     | -       |
| after catalysis  | 90     | 0.2      | 13    | 12.5    |
| CZAC/HZSM-5    |        |          |       |         |
| before catalysis | 135    | 0.2      | 7     | -       |
| after catalysis  | 80     | 0.1      | 9     | 12.5    |
| CZAZ/HZSM-5    |        |          |       |         |
| before catalysis | 135    | 0.2      | 7     | -       |
| after catalysis  | 82     | 0.1      | 16    | 13.2    |

Further, catalysts had a high surface area with a predominance of mesopores (Table 2). The CZA/HZSM-5 catalyst had a lower specific surface area compared to catalysts containing chromium and zirconium. The CZAC/HZSM-5 and CZAZ/HZSM-5 catalysts had the specific surface area of 135 m²/g and an average pore volume of 0.2 cm³/g. From the presented data it can be presence of chromium and zirconium, in the copper-containing catalyst for methanol synthesis, have led to a decrease in the size of the coherent-scattering region of the metallic copper phase [21].

Figures 2 and 3 show the desorption spectra of methanol and DME from the surface of CZAC, HZSM-5, and CZAC/HZSM-5 catalysts, accompanied by the mass spectrometric analysis of the desorption products (in the figures, the most important m/z are shown).

The maxima of the desorption of physically adsorbed methanol (m/z = 31, 32) for all three catalysts were observed on the TPSR spectrum after methanol adsorption (Figure 2a) at 165…175 °C. The spectrum of methanol desorption from the surface of CZAC had a broad peak with a maximum temperature of 197 °C. According to the mass spectrometric analysis (Figure 2), at this temperature, the desorbed gases contained CO₂ (m/z = 44), H₂O (m/z = 18), and H₂ (m/z = 2).

Fig. 2. (a) Methanol TPSR profiles and mass spectrometric analysis of desorption products: (b) from the surface of CZAC/HZSM-5; (c) from the surface of HZSM-5; (d) from the surface of CZAC.
The appearance of CO$_2$ and H$_2$ may be due to chemical adsorption and decomposition of methanol on the surface of the copper-containing catalyst under TPSR. According to [22], aldehyde and formate complexes, formed during the chemical adsorption of methanol on copper-containing systems, can be sources of CO and CO$_2$. Also, steam reforming of methanol by adsorbed water, remaining on the surface of the catalyst after its activation, was not ruled out.

The spectrum of temperature-programmed desorption of methanol from the surface of the methanol dehydration catalyst (Fig.2a, 2c) showed two most pronounced peaks at 175 °C and 261 °C. According to the mass spectrum data, physically adsorbed methanol (175 °C) and adsorbed water were released first. The maximum emission of DME (m/z = 45 and 46) and water, formed in the methanol dehydration reaction at the active sites of the zeolite, was observed at 261 °C.

The desorption spectrum of methanol from the BC surface had two peaks. The physically adsorbed methanol was released at 165 °C (Figures 2a and 2b). The intensive maximum at 241 °C was due to appearance of DME, hydrogen, and carbon dioxide. DME was formed as a result of the methanol dehydration on the zeolite component of the catalyst.

The formation of DME and water on the BC surface occurred at a lower temperature (241 °C) than on the zeolite (261 °C). At the same time, a maximum of desorption at 220...270 °C from the surface of the BC was accompanied by appearance of CO$_2$ and H$_2$. These products were formed as a result of surface reactions of methanol. In the same temperature range, methanol and ether could be reformed to form hydrogen and carbon dioxide [23-32]. According to the TPSR spectra, it was possible to suggest a synergistic effect of two components of the BC, which facilitates catalytic behaviour at their interfaces.

The TPSR spectra of DME from the surface of CZAC, HZSM-5, and CZAC/HZSM-5 are shown in Fig.3. The presence of two broad low-intensity desorption peaks at 150...220 °C and 220...500 °C, corresponding to appearance of CO$_2$ and H$_2$O on the mass spectrum, could be noted on the TPSR spectrum from the surface of the methanol synthesis catalyst.

The TPSR spectrum of DME from the surface of HZSM-5 had a peak at 283 °C with a broad shoulder at 112...255 °C. The broad shoulder in this temperature range was associated with DME desorption, accompanied by the release of water and hydrogen from various adsorption sites.

![Fig. 3](https://doi.org/10.1051/matecconf/201824300002)
The peak at 283 °C corresponded to desorption of carbon dioxide and water due to surface reactions. The TPSR spectrum of DME from the surface of the BC had a broad shoulder at 120–200 °C. This shape and position corresponded to the processes that occurred on the zeolite that were accompanied by desorption of DME and water. The intense peak with a maximum at 234 °C was due to desorption of DME, water, hydrogen, and carbon dioxide. Appearance of H₂ and CO₂ in the desorption products could be related to DME reforming on the surface of the BC. As is known, the hydrolysis of DME to methanol is possible on the acid catalyst, and methanol reforms to CO₂ and H₂ on the CuZnAl-oxide catalyst. The absence of DME hydrolysis on the zeolite was explained by the fact that the water necessary for the reaction occurred on the same surface sites of the BC. The BC promoted both direct and reverse conversion, which indicated its high catalytic activity and explained the high content of byproducts in products of the direct synthesis of DME.

Based on the literature [23, 24] and this study, it was possible to assume the following surface reactions:

\[ \text{CH}_2\text{OCH}_3 + \text{OHS} \leftrightarrow \text{CH}_3\text{OS} + \text{CH}_3\text{OH} \]
\[ \text{CH}_2\text{OCH}_3 + \text{OS} \leftrightarrow 2\text{CH}_3\text{OS} \]
\[ \text{CH}_3\text{OH} + \text{OHS} \leftrightarrow \text{CH}_3\text{OS} + \text{H}_2\text{O} \]
\[ \text{CH}_3\text{OS} + \text{OHS} \leftrightarrow \text{HCOOS} + \text{HS} + \text{H}_2 \]
\[ \text{CH}_3\text{OS} + \text{OS} \leftrightarrow \text{HCOOS} + 2\text{HS} \]
\[ \text{HCOOS} \leftrightarrow \text{CO}_2 + \text{HS} \]
\[ \text{HCOOS} + \text{OHS} \leftrightarrow \text{CO}_2 + \text{H}_2\text{O} \]
\[ \text{CH}_3\text{OS} \leftrightarrow \text{H}_2\text{CO} + \text{HS} \]
\[ \text{CH}_3\text{OS} + \text{OS} \leftrightarrow \text{H}_2\text{CO} + \text{OHS} \]
\[ \text{H}_2\text{CO} + 2\text{OS} \leftrightarrow \text{CO}_2 + \text{H}_2\text{O} \]
\[ \text{HS} + \text{HS} \leftrightarrow \text{H}_2 \]
\[ \text{HS} + \text{OHS} \leftrightarrow \text{H}_2\text{O} \]
\[ 2\text{OHS} \leftrightarrow \text{H}_2\text{O} + \text{OS} \]

4 Conclusion

Catalytic systems of the bifunctional type were obtained in the work. It was shown that BC obtained by physical mixing of CuZnAl(Cr/Zr)-Oₓ and HZSM-5 components were active in direct synthesis of DME from hydrogen and carbon oxide. Using physico-chemical methods, it was shown that the composition and the structure of the synthesized catalysts for the production of methanol and DME changed during catalysis. Structural rearrangements were observed as crystalline phases increased. Adding Cr and Zr caused the processes of structure formation in the catalysts in the reaction medium and were the structure-promoting additives.

When the data on the nature of the interaction of methanol and DME with the surface of the BC were taken into account, it could be noted that the catalyst exhibited the greatest catalytic activity at 240–260 °C.

According to the TPSR, the use of a BC made it possible to reduce the dehydration temperature of the methanol prepared from syngas as compared with the dehydration of methanol on the HZSM-5 catalyst. The resulting catalysts can be promising for use in industrial processes.

This research (project No. 8.2.10.2018) was carried out with the support of the Program of increasing the competitiveness of TSU.
