Seasonal variability of net sea-air CO₂ fluxes in a coastal region of the northern Antarctic Peninsula

Thiago Monteiro1,2,3, Rodrigo Kerr1,2,3,4 & Eunice da Costa Machado1,4

We show an annual overview of the sea-air CO₂ exchanges and primary drivers in the Gerlache Strait, a hotspot for climate change that is ecologically important in the northern Antarctic Peninsula. In autumn and winter, episodic upwelling events increase the remineralized carbon in the sea surface, leading the region to act as a moderate or strong CO₂ source to the atmosphere of up to 40 mmol m⁻² day⁻¹. During summer and late spring, photosynthesis decreases the CO₂ partial pressure in the surface seawater, enhancing ocean CO₂ uptake, which reaches values higher than −40 mmol m⁻² day⁻¹. Thus, autumn/winter CO₂ outgassing is nearly balanced by an only 4-month period of intense ocean CO₂ ingassing during summer/spring. Hence, the estimated annual net sea-air CO₂ flux from 2002 to 2017 was 1.24 ± 4.33 mmol m⁻² day⁻¹, opposing the common CO₂ sink behaviour observed in other coastal regions around Antarctica. The main drivers of changes in the surface CO₂ system in this region were total dissolved inorganic carbon and total alkalinity, revealing dominant influences of both physical and biological processes. These findings demonstrate the importance of Antarctica coastal zones as summer carbon sinks and emphasize the need to better understand local/regional seasonal sensitivity to the net CO₂ flux effect on the Southern Ocean carbon cycle, especially considering the impacts caused by climate change.

The investigation of Antarctic coastal regions has long been neglected because they are difficult to access1–4, especially during periods other than the austral summer5–8. This occurs because of most of the year, i.e., from April to November, these regions are almost completely or completely covered by sea ice9,10. Such conditions lead to a biased representation of sampling in autumn and winter, which are likely critical periods for changes in seawater carbonate chemistry and net sea-air CO₂ flux (FCO₂). In fact, several studies have been conducted during the austral summer to better understand the FCO₂11–16 and carbonate system parameter variability17–22 in the remote Southern Ocean. It is widely known that the Antarctic coasts behave as a strong CO₂ sink during the summer15,23, which has intensified during recent years14,15. Actually, the intensity of this behaviour is marked by high interannual variability, since the summer CO₂ fluxes in the Gerlache Strait, for example, oscillate between periods of strong CO₂ sink (i.e., < −12 mmol m⁻² day⁻¹) and sea-air near-equilibrium conditions at inter-annual scales25,26. However, even when Antarctic coastal regions do not behave as a strong CO₂ sink, they take up CO₂ in the summer15, although eventual episodes of CO₂ outgassing can occur20.

Although some studies have provided important information on the seasonality of the FCO₂7,8,19, they are restricted to a few specific years or localized regions, which may bias the modelled long-term trends of these regions. Hence, understanding the annual budget of sea-air CO₂ exchanges remains a challenge6,14. This is particularly true for the Gerlache Strait and likely other major embayments around the Antarctic coasts, since it remains unclear whether this CO₂ sink behaviour persists throughout the year or is balanced in other seasons. Moreover, little is known about the main drivers of FCO₂ seasonality and their consequences for the sea surface carbonate system. Therefore, here, we present an annual overview of the FCO₂ and the carbonate system properties in the Gerlache Strait, an ecologically and climatically important area of the northern Antarctic Peninsula (NAP). Furthermore, we demonstrate that this region acted as an annual net CO₂ source to the atmosphere from
2002 to 2017, contrasting with previous findings for the western Antarctic Peninsula environments\(^7,8,19\) and other regions around Antarctica\(^25–27\).

Oceanographic features of the Gerlache Strait

The Gerlache Strait is a coastal region along the NAP that is being impacted by climate change\(^24,28\) and is essential for the health of the Antarctic food web\(^29–31\). The strait is a shallow basin that lies between the NAP and the Palmer Archipelago and is connected to the Bellinghausen Sea (to the west) and the Bransfield Strait (to the north) (Fig. 1a,b). Although it covers a smaller area (~8000 km\(^2\)) than other coastal regions around the NAP, the Gerlache Strait is a highly productive coastal zone. In the Gerlache Strait, records of chlorophyll \(a\) (used as an indicator of primary producer biomass) range from ~2.0 mg m\(^{-3}\)\(^31\) to ~23 mg m\(^{-3}\)\(^32\) under distinct austral summer conditions. These concentrations have the same or a greater magnitude than those observed in more extensive regions, such as the Bransfield Strait (4.4 ± 3.84 mg m\(^{-3}\))\(^32\) and the northwestern Weddell Sea (1.38 ± 2.01 mg m\(^{-3}\))\(^33\). In addition, the Gerlache Strait has experienced intense diatom blooms reaching > 45 mg m\(^{-3}\) of chlorophyll \(a\)\(^32\). Although higher, this value is consistent with that recorded in the vicinity of Palmer Station, in the southernmost part of the Gerlache Strait, where the maximum chlorophyll \(a\) recorded was ~30 mg m\(^{-3}\)\(^34\).

The high biological productivity in this region, reflected at different trophic levels\(^35\), is mainly due to the complex interplay of its distinct water mass sources, sea ice dynamics, ocean circulation, nutrient-rich meltwater input and protection from severe weather conditions\(^36,37\). Additionally, the rapid effects of climate change\(^24,28,38\), a recent increase in glacial meltwater discharge\(^39\), and likely the advection of both organic and anthropogenic carbon around the NAP\(^21,40,41\) have influenced the coupled physical-biological processes changing the carbon biogeochemistry across the entire western Antarctic Peninsula shelf region\(^28,39\).

Moreover, the Gerlache Strait is affected by irregular intrusions of Circumpolar Deep Water (CDW; e.g., Refs.\(^36,42–44\)) (Fig. 1b). CDW is a warm, salty, poorly oxygenated and carbon- and nutrient-rich water mass flowing eastward with the Antarctic Circumpolar Current at intermediate and deep levels around the continent\(^43,45,46\). CDW intrusions along the western shelf of the Antarctic Peninsula are often associated with upwelling, mainly caused by shallow bathymetry\(^47\) and predominant wind systems\(^36\). These intrusions are also affected by modes of climate variability that regulate the intensity of winds in the Southern Ocean, such as the El Niño Southern Oscillation (ENSO) and Southern Annular Mode (SAM)\(^45,48,49\). During the positive phases of the SAM, the westerly winds are intensified, and the frequency and intensity of episodic CDW intrusions increase\(^45\). Conversely, under extreme ENSO, winds are weakened and cooled\(^48\), probably reducing CDW intrusions on the western shelf of the Antarctic Peninsula. Under any of these conditions, the physical properties of CDW change when it is mixed with cooler and less saline surface waters, originating the modified Circumpolar Deep Water (mCDW). At depths greater than 100 m, the Gerlache Strait is influenced by the mixing of water masses sourced from the Bellinghausen and Weddell seas. In addition to mCDW, the north of the strait is influenced by a modified variety of High Salinity Shelf Water (HSSW), which is cooler and more oxygenated than CDW\(^45,50\). HSSW is formed on the northwestern Weddell Sea continental shelf and is advected towards and along the Bransfield Strait by the Antarctic Coastal Current\(^50,51\). Signs of its presence at deep levels of the Gerlache Strait are an important aspect of the NAP because HSSW is younger than CDW, and the biogeochemical impact of mixing between the modified varieties of these waters is not yet completely understood\(^22,23\). However, a consequence of HSSW is...
the intrusion of anthropogenic carbon in deep levels of the strait\(^{25,26}\), which can intensify the ocean acidification process in the region.

**Results**

**Hydrographic properties and the carbonate system.** Negative sea surface temperatures were recorded from April to November (Fig. 2a), and the lowest values in summer were observed in the northernmost part of the strait, where the highest salinities were recorded (Figure S4). The opposite temperature distribution pattern occurred during spring, when the lowest temperatures were recorded at the southern end of the strait. At the connection between the central basin of the Gerlache Strait and the Bellingshausen Sea (i.e., Schollaert Channel), higher temperatures were associated with lower salinity (Figure S4). On the other hand, the spatial distributions of temperature and salinity in autumn and winter were more homogeneous than those in summer and spring. The carbonate system properties also demonstrated distinct spatial distribution patterns among seasons (Figures S5–S8). The seasonal variabilities of total alkalinity (\(A_T\)) and total dissolved inorganic carbon (\(C_T\)) followed that of seawater \(\text{CO}_2\) partial pressure (\(p\text{CO}_2^{sw}\)) and were inverse to those of pH and the calcite and aragonite saturation states (\(\Omega_{\text{Ca}}\) and \(\Omega_{\text{Ar}}\), respectively) throughout the year. \(A_T\) was higher than \(C_T\) from December to March and was lower than \(C_T\) during the rest of the year (Fig. 2d). This seasonal pattern was also observed for \(C_T\) saturation relative to the atmosphere; i.e., the difference (\(\Delta p\text{CO}_2\)) between \(p\text{CO}_2^{sw}\) and the \(\text{CO}_2\) partial pressure in the atmosphere (\(p\text{CO}_2^{atm}\)) was positive from April to November and negative from December to March (Fig. 2b). Minimum \(p\text{H}\) values (total scale) of \(7.99 \pm 0.02\) were observed in winter, while in the other seasons, they were equal to or greater than 8.00 (Fig. 2c). Undersaturated carbonate calcium conditions (i.e., \(\Omega_{\text{Ca}}\) less than 1) were not observed for either species during the seasonal cycle (Fig. 2c), although the lowest surface values of \(\Omega_{\text{Ca}}\) were recorded in winter, on average.

In summer, virtually all processes exerted some influence on the surface \(\text{CO}_2\) system, as shown by the wide dispersion of the salinity-normalized \(A_T\) and \(C_T\) (\(nA_T\) and \(nC_T\), respectively; Fig. 3a). In general, carbonate dissolution solves to exert a greater influence in autumn and winter than in spring and summer, although sea ice growth also acts to control \(A_T\) and \(C_T\) in winter. Carbonate dissolution/calcification processes were observed to play a role in changing the \(A_T\) and \(C_T\) surface distributions in spring, although sea ice growth and melting processes are also expected to exert an influence, mainly during October and November, in association with low temperatures (Fig. 3d) and high \(p\text{CO}_2^{sw}\). On the other hand, high temperatures (>0°C) in spring were associated with an increased influence of photosynthesis on the \(A_T\) and \(C_T\) (Fig. 3d).

**Drivers of \(p\text{CO}_2^{sw}\) seasonal changes.** \(C_T\) had the dominant effect on changes in \(p\text{CO}_2^{sw}\) throughout the year. \(A_T\) and temperature were secondary drivers of these changes, while salinity had a minor influence on surface \(p\text{CO}_2^{sw}\) (Fig. 4). In summer and spring, there was a considerable decrease in \(p\text{CO}_2^{sw}\), mainly due to the \(C_T\) drawdown. This decrease was compensated by the increasing effect on \(p\text{CO}_2^{sw}\) of the reduction in \(A_T\) and the increase in temperature. In winter and autumn, the considerable increase in \(p\text{CO}_2^{sw}\) was driven by the increase in \(C_T\) and partially compensated for by the increase in \(A_T\) and decrease in temperature.

**Net sea-air \(\text{CO}_2\) fluxes (\(\text{FCO}_2\)).** \(\text{FCO}_2\) exhibited distinct seasonality throughout the year, with the region swinging from a strong \(\text{CO}_2\) sink (\(\text{FCO}_2 < -12 \text{ mmol m}^{-2} \text{ day}^{-1}\)) in summer to a strong \(\text{CO}_2\) source (\(\text{FCO}_2 > 12 \text{ mmol m}^{-2} \text{ day}^{-1}\)) in winter (Fig. 5). During autumn and spring, the behaviour of the region oscillated between the major situations normally observed during winter and summer, resulting in a moderate \(\text{FCO}_2\). Despite this well-marked seasonality, the region was an annual weak \(\text{CO}_2\) source from 2002 to 2017, with an average estimated \(\text{FCO}_2\) of \(1.24 \pm 4.33 \text{ mmol m}^{-2} \text{ day}^{-1}\). Notably, with high spatial and temporal variability, this near-equilibrium condition was achieved because the region switched from a moderate to strong \(\text{CO}_2\) ocean sink from December to March to a moderate to strong \(\text{CO}_2\) source to the atmosphere throughout the rest of the year (Fig. 5). Months with the most intense \(\text{CO}_2\) uptake levels (<−12 mmol m\(^{-2}\) day\(^{-1}\)) have occurred more frequently since 2011, with the peak in January and February of 2016. On the other hand, months with the maximum \(\text{CO}_2\) outgassing (>12 mmol m\(^{-2}\) day\(^{-1}\)) seem to have become less frequent since 2009 (Fig. 5).

Considering all seasons between 2002 and 2017, high seasonal variability in \(\text{FCO}_2\) magnitude was identified (Fig. 6). However, the behaviour of the Gerlache Strait as a \(\text{CO}_2\) sink or source remained almost consistent within each season, as observed in summer (Fig. 6b) and winter (Fig. 6d). Only two particular exceptions occurred in the autumns of 2011 and 2014, when the region was a weak \(\text{CO}_2\) sink (Fig. 6c). Exceptions were also identified in spring, when the region behaved as a strong \(\text{CO}_2\) source in 2008 and a particularly strong \(\text{CO}_2\) sink in 2010 (Fig. 6e). Although the specific episodes in autumn did not appear to influence the average annual \(\text{FCO}_2\), the unusual spring \(\text{FCO}_2\) magnitudes coincided with increases in the average annual \(\text{FCO}_2\) in the respective years (Fig. 6a). The Gerlache Strait acted as an absolute annual \(\text{CO}_2\) source of \(4.4 \pm 2.8 \text{ mmol m}^{-2} \text{ day}^{-1}\) from 2002 to 2009 and has become predominantly a net annual \(\text{CO}_2\) sink of \(−2.0 \pm 3.0 \text{ mmol m}^{-2} \text{ day}^{-1}\) since 2010 (Fig. 6a).

A seasonal pattern in the spatial distribution of \(\text{FCO}_2\) along the Gerlache Strait was also identified. This pattern was characterized by a more homogeneous spatial distribution in autumn and winter (Fig. 7bc) than in summer and spring (Fig. 7ad). Moreover, the northernmost part of the strait, north of 64°5S, had a higher annual \(\text{FCO}_2\) (3±8 mmol m\(^{-2}\) day\(^{-1}\)) than the southernmost part of the strait, south of 65°5S. In the southernmost part, there was an annual \(\text{CO}_2\) uptake of \(-7 \pm 16 \text{ mmol m}^{-2} \text{ day}^{-1}\).

**Discussion**

**Seasonal changes in sea-air \(\text{CO}_2\) fluxes.** In late spring and summer, the Gerlache Strait is a \(\text{CO}_2\) sink, with rates ranging from \(-13 \pm 12 \text{ mmol m}^{-2} \text{ day}^{-1}\) in January to \(-5 \pm 9 \text{ mmol m}^{-2} \text{ day}^{-1}\) in March (Fig. 5). This strong \(\text{CO}_2\) uptake is driven by an increase in biological activity coupled with meltwater input (Fig. 8a)\(^{14,15,20,52–54}\).
Figure 2. Detrended annual cycle of hydrographic and carbonate system properties on the surface of the Gerlache Strait. (a) Temperature and salinity, (b) CO₂ partial pressure in the sea surface ($p_{CO_2}^{sw}$) and the difference between $p_{CO_2}^{sw}$ and atmospheric $p_{CO_2}$ ($\Delta p_{CO_2}$), (c) pH (total scale) and saturation states of calcite ($\Omega_{Ca}$) and aragonite ($\Omega_{Ar}$), and (d) total alkalinity ($A_T$) and total dissolved inorganic carbon ($C_T$). The blue bars are the standard deviations oriented up or down for visual clarity. The horizontal lines are the boundaries of 0 °C (a) and a $\Delta p_{CO_2}$ equal to 0 (b).
from December until late summer (Fig. 5), when sea ice formation becomes gradually more intense. This is revealed by the substantial CT drawdown (Fig. 4), which characterizes the influence of photosynthesis on the surface water, associated with a slight decrease in AT as a result of further respiration (Fig. 3b). Phytoplankton growth is favoured by the increased stability of the nutrient-rich shallower mixed layer in summer and late spring (Fig. 8a), mainly due to meltwater input. This is more evident in the southernmost part of the strait, where intrusions of warmer mCDW would likely lead to sea ice melting and the higher percentage of meteoric water (Figure S9) than in the northernmost region, which is comparatively ice-free (Figure S9). Hence, this could potentially account for the greater CO2 uptake in the southern region than in the northern region (Fig. 7). Nevertheless, the spatial variability of the carbonate system parameters is clearly greater in spring and summer than in autumn and winter. Therefore, it is likely that other oceanographic processes simultaneously have roles in changing the surface nAT and nCT.

In fact, during early spring, the carbonate dissolution/precipitation and sea ice growth/melt associated with low temperatures (Fig. 3d) seem to influence the carbonate system due to the increase in CT that is rejected through the sea ice brine. However, the impact of each of these processes, and even the presence of other involved processes, is not yet well understood. The dominant processes in spring (i.e., carbonate dissolution/precipitation or photosynthesis/respiration), as well as during other seasons, can also exhibit interannual variability. For example, during summer, there is variability in CO2 uptake oscillating between 2 and 4 years, by which FCO2 in the region alternates between strong CO2 sink and near-equilibrium conditions. This variability is associated with both intense biological activity and the intrusion of local upwelled CO2-rich waters (e.g., mCDW). In addition, it is linked to the influence of modes of climate variability, such as ENSO, which decreases the wind intensity, leading to favourable conditions for phytoplankton blooms. This explains why the most intense CO2...
Figure 4. Effects of total alkalinity (AT), total dissolved inorganic carbon (CT), sea surface temperature (SST) and sea surface salinity (SSS) on seawater pCO2 (pCO2sw) for each season in the Gerlache Strait. The variation in each parameter is calculated as the difference between the values of each parameter and their respective averages in previous seasons. The unit of all drivers is the same as that for pCO2sw (µatm), and their magnitudes represent their influence on pCO2sw changes. Positive values indicate that an increase in the parameter led to an increase in pCO2sw; negative values indicate that a decrease in the parameter led to a decrease in pCO2sw. The only exception to this is AT because an increase in AT leads to a decrease in pCO2sw and vice versa. The error bars (purple) show the difference between the sum of all drivers and the actual variation in pCO2sw (∆pCO2sw), indicating the extent to which the decomposition of pCO2sw into its drivers differs from ∆pCO2sw. More details are given in the methods section.

Figure 5. Monthly averages of net sea-air CO2 fluxes (FCO2) in the Gerlache Strait from January 2002 to December 2017 with an inset showing the variability throughout the year to characterize the seasonal cycle of FCO2 and the percentage of sea ice cover (filled blue bars). The gaps are from years when there was no winter sampling in the region. The blue bars oriented upwards are the standard deviations from the respective monthly averages, as are the black bars in the inset. Positive FCO2 values represent the outgassing of CO2 to the atmosphere, whereas negative FCO2 values represent CO2 uptake by the ocean.
uptake was recorded in 2016 (Fig. 5), as this was the year with the most extreme ENSO since 1998, which was associated with biogeochemical changes along the water column. Therefore, the same mechanism underlying the shift in the dominant physical processes may occur in other seasons of the year. This would likely explain why the region was an exceptionally strong CO2 source in spring 2008 but a strong CO2 sink in spring 2010 (Fig. 6e).

In autumn, the region becomes a moderate CO2 source to the atmosphere, with the maximum magnitude in August (14 ± 7 mmol m⁻² day⁻¹). Such behaviour is due to a significant increase in CT, which leads to an increase in pCO₂. This is further partially offset by the effect that the increase in AT has on pCO₂ (Fig. 4), implicating the upwelling process as a likely cause. In fact, more intense short-term irregular intrusions of mCDW coupled to the deeper mixed layer, which lead to intensified vertical mixing in the winter, are likely to carry CO₂-rich waters to the surface layer of the strait (Fig. 8b). Indeed, this has been the process most observed in other Southern Ocean coastal regions. On the western Antarctic Peninsula shelf, for example, there is no evidence of inorganic macronutrient regeneration in late summer, revealing that the increase in CT must be more associated with upwelling and/or advection processes. Although these mCDW intrusions can occur throughout the year and through virtually all connections of the Gerlache Strait, they are expected to be more intense in winter and at the southern end of the strait. In addition, the rejection of CT through sea ice brine is an important process (Fig. 8b). Despite occurring more intensely in winter than in other seasons, this process should also contribute to CO₂ release in autumn, as it was also dominant in controlling AT and CT (Fig. 3c). The increase in CT due to ice growth, first shown in a laboratory experiment, occurs in both Arctic and Antarctic regions, where there is an intense sea ice dynamic. Hence, the increase in CT leads to high pCO₂ values but is also related to decreases in ΩCa and ΩAr. Thus, these conditions contribute to maintaining a relatively low pH (≤ 8.00) until mid-spring, when sea ice begins to melt and both CT and pCO₂ decrease towards the summer season.

Although the spatial distribution of FCO₂ is more homogeneous in autumn and winter than in other seasons (Fig. 7), there is intense interannual variability in these fluxes (Fig. 6). It is not yet clear what drives this variability, but it has been linked to sea ice cover variability in other Antarctic regions. This link makes sense due to the good correlation (r² = 0.73; p = 0.0006; n = 12) of the FCO₂ seasonal cycle with the sea ice cover seasonality in

![Figure 6](https://www.nature.com/scientificreports/)
the Gerlache Strait, mainly in the months when it acts as a CO2 source ($r^2 = 0.93; p = 0.0136; n = 7$) (Figure S10). Despite the strong CO2 outgassing during these periods, sea ice cover constrains sea-air CO2 exchanges8,26, leading to the conclusion that this CO2 outgassing could be even more intense under sea ice-free conditions, as observed in the Arctic Ocean67. Hence, the FCO2 dynamics in sea ice-covered periods may be more sensitive than previously thought.

**Seasonality of the carbonate system and acidification process.** The carbonate system parameters on the surface of the strait follow seasonal FCO2 dynamics, that is, sea ice dynamics. The lower pH, $\Omega_{\text{Ca}}$ and $\Omega_{\text{Ar}}$ values in winter than in other seasons, although expected, reinforce the biogeochemical sensitivity of this sea-son. The low temperatures and the brine released by sea ice growth lead to the dissolution of calcium carbonate and decreases in $\Omega_{\text{Ca}}$ and $\Omega_{\text{Ar}}$19. However, we did not find the calcium carbonate in the surface of the Gerlache Strait to be in a subsaturated state, even in winter when there was high $p$CO$_2$; this was also the case in Ryder Bay18,19, a region located farther south on the western Antarctic Peninsula shelf, which is under dynamic conditions similar to those of the Gerlache Strait. In summer, carbonate mineral supersaturation is associated with regions where there is strong CO2 uptake, such as in the southernmost portion of the strait, where meteoric water input is most intense (Figure S9) and salinity is relatively low (Figures S4 and S7). This reveals that the intense $p$CO$_2$ drawdown caused by biological activity outweighs the increase in $p$CO$_2$ by the effect of carbonate precipitation18, and carbonate dissolution is minimized due to the biological uptake of CT. Nevertheless, the sensitivity of these parameters should be observed in more detail, as carbonate calcification and dissolution processes also seem to play an important role in controlling $A_2$ and $C_p$ (Fig. 3b,c). Furthermore, because we found minimum pH values in winter (7.92) lower than those at Ryder Bay in 1994 (8.11) and 2010 (8.00)7 as well as between 2011 and 2014 (7.95)19, these waters may be experiencing ocean acidification, although counterintui-

![Figure 7. Surface distribution of the net sea-air CO2 flux (FCO2) in the Gerlache Strait from 2002 to 2017 in (a) summer, (b) autumn, (c) winter and (d) spring. Positive FCO2 values represent the outgassing of CO2 to the atmosphere, whereas negative FCO2 values represent CO2 uptake by the ocean. The numbers indicate the averages and standard deviations of FCO2 in each season. The black continuous and dashed isolines depict the FCO2 values of –12 and +12 mmol m$^{-2}$ d$^{-1}$, respectively, for the strong CO2 sink and outgassing situations. These maps were generated by using the software Ocean Data View (v. 5.3.0, https://odv.awi.de)100.](image-url)
tive processes may be offsetting the effects in the studied region\textsuperscript{22}. In fact, the waters of the Gerlache Strait have previously been reported to show signs of acidification in summer below the mixed layer\textsuperscript{20,22}, with surface pH values lower than those found at Ryder Bay (8.21–8.48\textsuperscript{18}).

The effects of intensified summer CO\textsubscript{2} uptake on calcite and aragonite saturation in surface waters may emerge in the coming years. However, supersaturation of these carbonate species is associated with decreased pCO\textsubscript{2,sw} values in summer\textsuperscript{15}. This reveals that these feedback effects need to be further investigated, especially considering the residence time of these waters in coastal regions. As strong summer CO\textsubscript{2} sink periods are extended, an inverse effect of sea surface acidification may occur, as observed in the southernmost portion of the Gerlache Strait. Nevertheless, the acidification process should occur in the deep layers of these strong CO\textsubscript{2} sink regions and in adjacent deep waters due to horizontal advection. Indeed, this will likely be the case because the residence time of surface waters in this region was estimated to be less than 7 days, while the residence time in adjacent larger basins ranges between 13 and 40 days\textsuperscript{30}. Therefore, assuming a steady increase in both atmospheric CO\textsubscript{2} and temperature\textsuperscript{29}, the Southern Ocean coastal regions may become intense hotspots of deep-ocean acidification, with some expected implications for organisms throughout the water column and the food web as a whole. For example, on the sea surface, there may be a restructuring of the food web due to a shift in the dominant groups.
of phytoplankton, such as from diatoms to smaller organisms [Refs.24,53 and references therein]. Such changes will potentially decrease the transfer of carbon, energy and nutrients through organisms such as diatoms to pelagic and benthic ecosystems, with complex feedbacks on ocean biogeochemistry and climate41. In this sense, these findings shed light on the importance of clarifying the real impacts of these changes throughout the water column. This is because, despite showing signs of acidification, most studies provide only snapshots, and coupled ocean–land–ice processes can mask the real ocean acidification state of Southern Ocean coastal regions.

**Annual budget of sea-air CO₂ exchanges.** We have identified the Gerlache Strait as a weak CO₂ source from 2002 to 2017, with an annual budget of sea-air CO₂ exchanges at near-equilibrium conditions. This contrasts with the expectations for other Antarctic coastal regions, which demonstrate annual CO₂ sink behaviour5,13,25, such as in summer and spring1,14,33. The studied region acts as a moderate CO₂ source in autumn and a strong CO₂ source in winter. The CO₂ outgassing that occurs during 8 months of the year (i.e., from April to November) is almost fully compensated for in only 4 months (i.e., from December to March), when the region acts as a moderate to strong CO₂ sink. Although this behaviour is not considered typical for Antarctic coastal regions, the Gerlache Strait lies at approximately 64°S, where Takahashi et al.70 verified an approximately neutral annual sea-air CO₂ flux. Nevertheless, here, we hypothesize that this scenario is more common to coastal regions of the Southern Ocean than previously thought because incipient signs of this behaviour have already been identified in other Antarctic coastal regions. For example, Bakker et al.26 found strong supersaturation of seawater CO₂ relative to atmospheric CO₂ in autumn and winter in the Weddell Sea but suggested that the region was an annual CO₂ sink. These contrasting summer/winter behaviours, with an annual CO₂ sink budget, also extend to other Southern Ocean coastal regions, such as the western Antarctic Peninsula42,53,61, the Ross Sea1,30, the Indian Antarctic sector24,25 and even the Antarctic Zone south of 62°S as a whole42. However, the relatively low monthly and interannual coverage in most of these studies may have biased the integrated FCO₂ budget throughout the year. This is particularly true if we take into account recent estimates of FCO₂ from long-term climatology for global coastal regions3. In this climatology, the NAP, as well as the Weddell Sea and much of the Atlantic and Indian sectors of the Southern Ocean, was a net CO₂ source between 1998 and 2015. Despite this, the CO₂ uptake by CO₂ sink regions was so intense that the annual FCO₂ budget for this period was approximately −17 Tg C year⁻¹14.

**Expected scenarios for the future of sea-air CO₂ exchanges.** The recent changes observed in the NAP, mainly related to the intensification of the westerly winds49, rising temperatures73 and the prolongation of ice-free water periods74,75, are expected to persist in the coming years24,28. In this sense, two future scenarios for net sea-air CO₂ fluxes can be projected. First, with longer ice-free water periods, these coastal regions could release CO₂ that would otherwise remain in the seawater isolated by sea ice, intensifying the annual CO₂ source. This release may be enhanced by intensified mCDW intrusion into the western Antarctic Peninsula shelf that have been projected24,45, although little is known about its periodicity and variability. On the other hand, nutrient-rich mCDW intrusions coupled with the delayed sea ice cover period and rising temperatures should lead to prolonged phytoplankton growth75. Thus, strong CO₂ sink periods should also extend beyond late summer. As CO₂ uptake has intensified in the summer14,15 and proved to nearly counteract annual CO₂ evasion, this region could become an annual CO₂ sink in future years, particularly assuming that the Southern Ocean is becoming greener75. Actually, this second scenario seems likely to occur, as the magnitude and frequency of FCO₂ in months when the region is a strong CO₂ sink are increasing and in months when the region is a strong CO₂ source have been less frequent (Fig. 5), leading to intensified annual CO₂ uptake since 2010 (Fig. 6a).

These scenarios become more complex when we take into account the influence of the modes of climate variability. For example, the positive phase of SAM has been associated with more intense CO₂ outgassing due to the deepening of the mixed layer6. Conversely, it was also associated with higher CO₂ uptake due to the intensification of upwelling, which supplies iron and nutrients to the sea surface and hence increases phytoplankton growth77. This reveals the sensitivity of sea-air CO₂ exchanges to these feedback mechanisms and the urgent need to broaden investigations for a coupled analysis of ocean-climate systems. Nevertheless, signs of intensifying summer CO₂ sink behaviour6,15 suggest that the influence of SAM should be reversing the flux to encourage annual net CO₂ uptake in Antarctic coastal regions.

**Methods**

**Dataset and carbonate system properties.** We used the data available from Surface Ocean CO₂ Atlas version 6 (SOCATv6)78 to compile a temporal series spanning 2002 to 2017 (Figure S2) of the sea surface (up to a depth of 5 m) temperature (SST), salinity (SSS) and seawater CO₂ partial pressure (pCO₂(sw)) of the Gerlache Strait. Here, we evaluated the seasonal variability of the net sea-air CO₂ flux (FCO₂) and hydrographic and carbonate system parameters. Therefore, the seasons were defined as (1) summer: January to March; (2) autumn: April to June; (3) winter: July to September; and (4) spring: October to December. We analysed the months in which the data covered the majority of the Gerlache Strait in all seasons (Figure S3).

The pCO₂(sw) data extracted from SOCATv6 were directly measured using air–water equilibrators and an infrared analyser for CO₂ quantification79. However, SOCATv6 provides surface pCO₂(sw) data with only corresponding SST and SSS values. Hence, we used total alkalinity (AT) from the High Latitude Oceanography Group (GOAL)79 and the World Data Center PANGAEA80 to estimate AT from SSS using Eq. 1 (r² = 0.98, RMSE = 4.4, n = 140).

\[
A_T = 36.72 \times SSS + 1052
\]

These data were sampled in the austral summers of 1995/96 (PANGAEA; https://doi.pangaea.de/10.1594/PANGAEA.825645;44) and 2015–2019 (GOAL; Table S1;52,22). Equation 1 was developed using the curve fitting toolbox of MATLAB, with the least absolute residual mode and first-order polynomial adjustment. This
Table 1. Average differences (Δ) and standard deviations for the sea surface temperature (SST; °C), salinity (SSS), total alkalinity (AT; μmol kg⁻¹), and total dissolved inorganic carbon (CT; μmol kg⁻¹) involved in seawater CO₂ partial pressure (pCO₂sw; μatm) changes. The table shows the differences between the values of the parameters in each season and their respective averages in previous seasons (ΔpCO₂sw).

|          | Summer          | Autumn         | Winter         | Spring         |
|----------|-----------------|----------------|----------------|----------------|
| ΔSST     | 1.47 ± 0.62     | −1.86 ± 0.59   | −0.80 ± 0.34   | 0.86 ± 0.88    |
| ΔSSS     | −0.33 ± 0.48    | 0.34 ± 0.25    | 0.25 ± 0.20    | −0.26 ± 0.29   |
| ΔAT      | −12 ± 18        | 12 ± 9         | 9 ± 7          | −9 ± 11        |
| ΔCT      | −50 ± 52        | 62 ± 14        | 25 ± 10        | −36 ± 42       |
| ΔpCO₂sw  | −69 ± 70        | 87 ± 24        | 38 ± 22        | −55 ± 70       |

Drivers of pCO₂sw changes. The pCO₂sw drivers throughout the seasons were calculated based on the difference between the values of the parameters in each season and their respective averages in previous seasons (ΔpCO₂sw; Table 1). Then, the ΔpCO₂sw values were separated into categories representing the contributions of differences in CT, AT, SST and SSS. The relative contributions of the drivers changing pCO₂sw were assessed by converting their relative changes into pCO₂sw units (μatm) following Lenton et al. as in Eq. 2:

\[
\Delta p_{CO_2}^{sw} = \partial p_{CO_2}^{sw}/\partial CT \cdot \Delta CT + \partial p_{CO_2}^{sw}/\partial AT \cdot \Delta AT + \partial p_{CO_2}^{sw}/\partial SST \cdot \Delta SST + \partial p_{CO_2}^{sw}/\partial SSS \cdot \Delta SSS
\]  

(2)

where ΔCT, ΔAT, ΔSST and ΔSSS are the differences between the values of the parameters and their respective averages in previous seasons. This analysis was conducted in each year, and the results were averaged to represent an average year. The partial derivatives were calculated using Eqs. 3 to 6 (see details in Takahashi et al.). These approximations have been widely used in the Southern Ocean to evaluate pCO₂sw drivers, both seasonally and spatially. Here, we used the average Revelle and Alkalinity factors of 14 and −13, respectively.

\[
\partial p_{CO_2}^{sw}/\partial CT = p_{CO_2}^{sw}/CT \times \text{Revelle factor}
\]

(3)

\[
\partial p_{CO_2}^{sw}/\partial AT = p_{CO_2}^{sw}/AT \times \text{Alkalinity factor}
\]

(4)

\[
\partial p_{CO_2}^{sw}/\partial SSS \approx 0.026 \times p_{CO_2}^{sw}
\]

(5)

\[
\partial p_{CO_2}^{sw}/\partial SST \Delta SST \approx 2 \times p_{CO_2}^{sw} \times \left(e^{0.0423 \times \Delta SST} - 1\right)
\]

(6)

Net sea-air CO₂ flux (FCO₂). We calculated FCO₂ using Eq. 7:

\[
FCO_2 = K_v \times K_s \times (1 - Ice) \Delta p_{CO_2}
\]

(7)

where ΔpCO₂ is the difference between pCO₂sw and atmospheric pCO₂ (pCO₂atm); K_v is the gas transfer velocity, depending on wind speed; K_s is the CO₂ solubility coefficient, as a function of both SST and SSS; and Ice is a dimensionless coefficient corresponding to the fraction of the air–water interface (between 0 and 1) covered by sea ice. We used monthly averages of pCO₂sw and wind speed (m s⁻¹) data from the U.S. Palmer Station, located in the southern part of the Gerlache Strait. The station continuously measures meteorological parameters throughout the year. We calculated pCO₂sw from the monthly averages of the atmospheric molar fraction of CO₂ (xCO₂atm) and atmospheric pressure (both from the Palmer Station), which was corrected by the water vapour pressure estimated from SST and SSS by the widely used equations of Weis and Price. Sea ice cover was obtained from the monthly mean of the 0.25° daily satellite products by Reynolds et al., which cover the entire length of the Gerlache Strait (Figure S9e–h).
Table 2. Average and standard deviation of the uncertainties propagated in the calculations of the carbonate system properties and net sea-air CO2 flux (FCO2) for each season. The units of uncertainty are the same as the units of the evaluated parameters: FCO2 (mmol m⁻² day⁻¹), total dissolved inorganic carbon (CT; μmol kg⁻¹), pH (total scale) and saturation states of calcite (ΩCa) and aragonite (ΩAr) (unitless). Standard deviations ~ 0 are smaller than the limit of significant digits in the averages.

|                  | Summer          | Autumn          | Winter          | Spring          |
|------------------|-----------------|-----------------|-----------------|-----------------|
| FCO2             | 1.96 ± 0.64     | 2.65 ± 0.83     | 3.46 ± 1.18     | 2.34 ± 0.76     |
| CT               | 5.58 ± 0.57     | 5.00 ± 0.10     | 4.84 ± 0.05     | 5.13 ± 0.46     |
| ΩCa < 2 μatm     | 0.15 ± 0.03     | 0.12 ± 0.01     | 0.11 ± 0.003    | 0.12 ± 0.03     |
| ΩCa < 5 μatm     | 0.10 ± 0.02     | 0.07 ± 0.0   | 0.07 ± 0.0   | 0.08 ± 0.02     |
| pH               | 0.0076 ± 0.0003 | 0.0075 ± 0.0003 | 0.0075 ± 0.0002 | 0.0075 ± 0.0002 |
| FCO2 < 2 μatm    | 4.15 ± 0.73     | 6.53 ± 2.10     | 8.29 ± 3.04     | 5.44 ± 1.80     |
| FCO2 < 5 μatm    | 6.11 ± 1.16     | 5.22 ± 0.13     | 5.02 ± 0.07     | 5.45 ± 0.83     |
| ΩAr < 2 μatm     | 0.16 ± 0.04     | 0.12 ± 0.01     | 0.11 ± 0.003    | 0.13 ± 0.03     |
| ΩAr < 5 μatm     | 0.10 ± 0.02     | 0.07 ± 0.0   | 0.07 ± 0.0   | 0.08 ± 0.02     |
| pH               | 0.0097 ± 0.0015 | 0.0087 ± 0.0015 | 0.0086 ± 0.0001 | 0.0090 ± 0.0010 |

Spatial distributions of properties. All spatial distribution maps for the properties in this study were interpolated using Data-Interpolating Variational Analysis (DIVA) gridding⁶⁰. We used a length scale value of 15% for both the X and Y axes to ensure optimal preservation of data structure and smoothness. The averaging and all other calculations performed in this study were based only on the observed or reconstructed data and not on the interpolated data. Map interpolations were made to provide reader-friendly visualization of the results.

Limitations and uncertainties. We estimated the propagated uncertainty from the partial derivatives of all calculated parameters (Table 2) in relation to each variable involved in the calculation as follows:

$$\sigma_f(x) = \sqrt{\left( \frac{\partial f(x)}{\partial \text{variable } a} \right)^2 \sigma_a^2 + \left( \frac{\partial f(x)}{\partial \text{variable } b} \right)^2 \sigma_b^2 + \cdots + \left( \frac{\partial f(x)}{\partial \text{variable } z} \right)^2 \sigma_z^2}$$

(8)

where the derived functions f(x) are the calculated parameters (i.e., FCO2, CT, Ω and pH) and σ is the uncertainty associated with each variable involved in calculation of the parameter. Because SSS uncertainties are expected to be low enough to be negligible (i.e., < 0.001, according to the GOAL and PANGAEA datasets), they were not considered here. Hence, the propagated uncertainties in CT, Ω and pH fundamentally represented the errors associated with the estimated AT (± 4.4 μmol kg⁻¹), SST (± 0.05 °C) and measured pCO2sw⁶⁸. We used pCO2sw data from SOCATv6 with uncertainties < 2 μatm (55% of total) and < 5 μatm (45%). We calculated the propagated uncertainties for all carbonate system properties with the CO2SYS error tool⁹⁶. For FCO2, uncertainty was related to the standard error of the averaged wind speed for each season, the measured pCO2sw and xCO2air measurements from the U.S. Palmer Station was estimated to be ± 0.07 μmol/mol for the studied period⁶⁸. Sea ice concentrations were computed to a precision of 1% coverage⁴⁹.

Finally, we used a first-order polynomial relationship between AT and SSS to estimate AT and calculate the other parameters of the carbonate system based on summertime data. We assumed this relationship for all seasons because the summer was the only period with available AT data for the study region. However, the summer is characterized by greater AT variability than other seasons, implying that the ranges of AT and SSS may represent the annual range (i.e., AT: 2200–2320 μmol kg⁻¹; SSS: 32–34.5). Such limitations are mainly due to the scarcity of data in periods other than summer and highlight the need for additional efforts to better understand the dynamics of the carbonate system parameters in coastal regions of the Southern Ocean.

Acknowledgements
This study contributes to the activities of the Brazilian Ocean Acidification Network (BrOA; www.broa.furg.br) and the Brazilian High Latitude Oceanography Group (GOAL; www.goal.furg.br), which is part of the Brazilian Antarctic Program (PROANTAR). GOAL has been funded by and/or has received logistical support from the Brazilian Ministry of Science, Technology, and Innovation (MCTI), the Brazilian Navy, the Secretariat of the Interministerial Commission for the Resources of the Sea (SECIRM), and the Council for Research and Scientific Development of Brazil (CNPq) through grants from the Brazilian National Institute of Science and Technology of Cryosphere (INCT-CRIOSFERA; CNPq Grants Nos. 573720/2008-8 and 465680/2014-3; EAPRGS Grant no. 17/2551-0000518-0), NAUTILUS, INTERBIOTA, PROVOCCAR and ECOPELAGOS projects (CNPq Grants Nos. 405869/2013-4, 407889/2013-2, 442628/2018-8 and 442637/2018-7, respectively), and Higher Education Personnel Improvement Coordination (CAPES Grant No. 23038.001421/2014-30). T.M. received financial support from PhD Grant No. 88887.360799/2019-00 from CAPES. R.K. received financial support from researcher Grant No. 304937/2018-5 from CNPq and 888881.195000/2018-01 from CAPES. We are thankful for the resources provided by CAPES to support the Graduate Program in Oceanology. We appreciate the availability of high-quality data from the SOCATv6, PANGAEA and Palmer Station datasets. Special thanks to the scientists (Taro Takahashi, Colm Sweeney, David Munro, Stu Sutherland, Timothy Newberger, Steven van Heuven, Mario Hoppema, Vassilis Kitidis and Ian Brown) onboard the RV Lawrence M. Gould, Nathaniel B. Palmer, Polarstern and James Clark Ross, who provided the surface ocean pCO2 measurements publicly available via the SOCAT dataset. We thank all researchers and students from LEOC/FURG and other GOAL groups for their contributions to cruise planning, sampling, and analyses. We also thank the Brazilian Navy, especially the crew onboard the RV Almirante Maximiano, for providing logistical and sampling support during the NAUTILUS and INTERBIOTA cruises.

Author contributions
T.M. conducted the data analysis and main interpretations of this study as part of his PhD thesis. R.K. supervised T.M. in conducting this study. He also planned and was the PI onboard the GOAL cruises. E.M. contributed as an expert in carbonate system and biogeochemical processes. All authors contributed to the interpretation of results and writing the manuscript as experts on marine CO2 systems.
