Background: Point mutations in mitochondrial genome cause severe clinical disorders.

Results: We designed recombinant RNA molecules imported into mitochondria of human cells, which are able to decrease the proportion of mitochondrial DNA molecules bearing a pathogenic point mutation.

Conclusion: Imported recombinant RNAs can function as anti-replicative agents in human mitochondria.

Significance: This is a new approach for therapy of mitochondrial diseases.

Defects in mitochondrial genome can cause a wide range of clinical disorders, mainly neuromuscular diseases. Presently, no efficient therapeutic treatment has been developed against this class of pathologies. Because most of deleterious mitochondrial mutations are heteroplasmic, meaning that wild type and mutated forms of mitochondrial DNA (mtDNA) coexist in the same cell, the shift in proportion between mutant and wild type molecules could restore mitochondrial functions. Recently, we developed mitochondrial RNA vectors that can be used to address anti-replicative oligoribonucleotides into human mitochondria and thus impact heteroplasmy level in cells bearing a large deletion in mtDNA. Here, we show that this strategy can be also applied to point mutations in mtDNA. We demonstrate that specifically designed RNA molecules containing structural determinants for mitochondrial import and 20-nucleotide sequence corresponding to the mutated region of mtDNA, are able to anneal selectively to the mutated mitochondrial genomes. After being imported into mitochondria of living human cells in culture, these RNA induced a decreased proportion of mtDNA molecules bearing a pathogenic point mutation in the mtDNA ND5 gene.

RNA is increasingly used in therapeutic applications, including the agents of RNA interference, catalytically active RNA molecules, and RNA aptamers that bind proteins and other ligands (reviewed in Ref. 1). Here, we use RNA molecules imported into human mitochondria to suppress negative effects of mutations in mtDNA. Involving in many metabolic pathways varying from cellular respiration to apoptosis, mitochondria are subcellular organelles essential for eukaryotic cells containing their proper genome, mtDNA. Human mtDNA is a closed circular double-stranded molecule of 16.5 kb able to replicate autonomously and encoding only 13 polypeptides, two ribosomal RNA (12 S and 16 S), and 22 tRNA, with the vast majority of mitochondrial proteins and several RNAs being encoded in the nucleus and imported from the cytoplasm. Multiple alterations may occur in the mitochondrial genome (deletions, duplications, and point mutations), resulting in severe impact on cellular respiration and therefore leading to many diseases, essentially muscular and neurodegenerative disorders. To date, >250 pathologic diseases were shown to be caused by defects in mtDNA (2). The majority of these mutations are heteroplasmic, meaning that mtDNA coexists in two forms, wild type and mutated, in the same cell. The occurrence and severity of pathologic effects depend on the heteroplasmy level, clinical symptoms appearing at the threshold of the order of 60 to 80%, depending on the mutation and the type of cells (3).

Various strategies have been proposed to address these pathologies, unfortunately, for the vast majority of cases, no efficient treatment is currently available. In some cases, defects may be rescued by targeting into mitochondria nuclear DNA-expressed counterparts of the affected molecules, an approach called allotopic strategy (4, 5). Allotopic expression of mtDNA-encoded polypeptides has been demonstrated in yeast, but in mammalian mitochondria, results are contradictory (reviewed...
Mitochondrial Import of RNA as a Therapeutic Tool

in Ref. 6). We have exploited the RNA mitochondrial import pathway, which is the only known natural mechanism of nucleic acid delivery into mitochondria (reviewed in Ref. 7), to develop two successful models of allotopic rescue of an mtDNA mutation by targeting recombinant tRNA into mitochondria (8, 9).

Another strategy that might be termed as “anti-genomic,” which consists of addressing into mitochondria endonucleases specifically eliminating mutated mtDNA, was also described (10, 11). Another approach, referred to as anti-replicative, aims to induce a shift in heteroplasmy level by targeting specifically the replication of mutant mtDNA, thus giving a propagative advantage to wild type genomes. This strategy has first been tested in vitro using peptide nucleic acids with high affinity to mutant mtDNA (12). It was demonstrated that peptide nucleic acid oligomers complementary to mutant mtDNA can specifically inhibit its replication in vitro; however, it remained non-applicable to living cells because of the impossibility of introducing peptide nucleic acid molecules into mitochondria in vivo (13). To overcome this obstacle, we proposed to use RNA mitochondrial import.

Analysis of the yeast tRNA\(^{\text{35S}}\)\(^{\text{CUU}}\) mitochondrial import mechanism demonstrated that binding to mitochondrial targeting protein factors and subsequent RNA translocation across mitochondrial membranes require formation of an alternative structure, different from a classic L-form tRNA model, characterized by bringing together the 3’-end and TΨC loop and forming the structure referred to as F-hairpin. Exploiting these data, we designed a short synthetic RNA comprising two domains of the yeast tRNA\(^{\text{35S}}\)\(^{\text{CUU}}\) alternative structure, d-arm and F-hairpin (referred to as FD RNA) (see Fig. 1), characterized by a high efficiency of mitochondrial targeting (14). These molecules, fused to oligonucleotide stretches complementary to the mtDNA-mutated region, were able to shift a heteroplasmy level in cells containing a large deletion in mtDNA, providing the first validation of the anti-replicative approach in vivo (15).

Here, we show that this approach is not limited to large rearrangements in mtDNA but can be applied to point mutations. We provide a protocol to design an oligonucleotide able to anneal to mtDNA bearing a point mutation but not to wild type mtDNA and an original assay to test the specificity of hybridization in vitro. A series of recombinant molecules, including RNA-DNA chimera, have been tested for mitochondrial import in human cultured cells and their ability to induce a shift of the heteroplasmy level. We demonstrate that RNA molecules containing mitochondrial targeting determinants and a 20-nucleotide sequence corresponding to the mutated region of mtDNA are able to selectively target mutated mitochondrial genomes. After being imported into mitochondria of cultured trans-mitochondrial human cells bearing a pathogenic point mutation in NDS gene, these RNA significantly decreased the proportion of mutated mtDNA molecules.

EXPERIMENTAL PROCEDURES

Recombinant RNA Modeling and Synthesis—To predict secondary structures of recombinant RNA and estimate their free energy (dG), we used the IDT Sci-Tools OligoAnalyser (version 3.1), and ViennRNA platforms were used. To estimate melting temperatures for DNA-DNA and RNA-DNA duplexes, we used the IDT Sci-Tools OligoAnalyser software (version 3.1) (17).

The recombinant RNAs were obtained by T7 transcription using the T7 RiboMAX Express Large Scale RNA Production System (Promega) on the corresponding PCR products and were gel-purified. For PCR, the following oligonucleotides containing a T7 promoter (underlined) were used: FD16L (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCA AAG GCC ACA TGA GCC CCC TAC AGG GCT C-3’); FD16H (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCG CGC ATG TGG CCT TTG GAG TGA GCC CCC TAC AGG GCT C-3’); FD25L (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCG CGC ATG TGG CCT TTG GAG TGA GCC CCC TAC AGG GCT C-3’); FD25H (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCG CGC ATG TGG CCT TTG GAG TGA GCC CCC TAC AGG GCT C-3’); FD20H (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCG CGC ATG TGG CCT TTG GAG TGA GCC CCC TAC AGG GCT C-3’); FD20L (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCG CGC ATG TGG CCT TTG GAG TGA GCC CCC TAC AGG GCT C-3’); FD20L (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCG CGC ATG TGG CCT TTG GAG TGA GCC CCC TAC AGG GCT C-3’); FD20H (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCG CGC ATG TGG CCT TTG GAG TGA GCC CCC TAC AGG GCT C-3’); FD20L (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCG CGC ATG TGG CCT TTG GAG TGA GCC CCC TAC AGG GCT C-3’); FD20H (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCG CGC ATG TGG CCT TTG GAG TGA GCC CCC TAC AGG GCT C-3’); FD20L (5’-TAA TAC GAC TCA CTG TAG CGC ACT CCG CGC ATG TGG CCT TTG GAG TGA GCC CCC TAC AGG GCT C-3’).

To test recombinant RNA annealing to target mtDNA, fragments of wild type and mutant mtDNA were amplified using primers hmtGluRT (5’-GTT CTG GAA ATA CAC C-3’) and CRC-F (5’-CAT CCT TAC CAC TAC AAT C-3’), separated on 1% agarose gel, blotted to Hybond-N membrane, and hybridized with \(^{32}P\)-labeled recombinant RNAs in 1× PBS at 37 °C. After PhosphorImager quantification (Typhoon Trio, GE Healthcare), the hybridization signals were normalized to amounts of corresponding mtDNA fragments calculated after ethidium bromide staining of the agarose gel (before transfer to Hybond membrane) by densitometry using G-Box and GeneTools analysis software. Thereafter, hybridization specificity was calculated for each RNA as one minus ratio between normalized signals for wild type and mutated DNA fragments. Thus, for recombinant RNA annealed only to mutant DNA fragment, the hybridization specificity value reached 1, and for RNA annealed equally to mutant and wild type fragments, this value was close to 0. At least three independent experiments were performed for each RNA.

Chimeric Oligonucleotide Synthesis—Chimeric oligonucleotides D20L DNA and D20H DNA were synthesized on an automatic ASM-800 RNA/DNA synthesizer (Biosset) at 0.4-μmol scale using solid phase phosphoramidite synthesis protocols (18) optimized for this instrument. The DNA and 2’-O-TBDMS (tert-butyldimethylsilyl)-protected RNA phosphoramidites and appropriate supports were purchased from Glen Research. A 5-ethylthio-\(H\)-tetrazole has been used as activator with 5- and 10-min coupling steps, respectively. After standard deprotection, oligonucleotides were purified by 12% polyacrylamide/8 mol urea gel and characterized by MALDI-TOF mass spectrometry (Autoflex III, Bruker Daltonics).
Synthesis of Fluorescently Labeled RNA Transcript—Alexa Fluor 488-5 UTP (Molecular Probes) was incorporated into RNA during 2-h T7 transcription by T7 RNA polymerase (Promega). A reaction mixture of 20 μl total volume contained 0.5 μg of DNA template, 80 units of T7-RNA polymerase (two additions of 40 units each), 0.5 mM ATP, 0.5 mM CTP, 0.5 mM GTP, 0.37 mM UTP, 0.125 mM Alexa Fluor 488-5-UTP, 10 mM DTT, and 40 units of RNaseOUT (Invitrogen). T7 transcript was purified by PAGE. To check the incorporation of the label in purified transcript, we compared the dye absorbance at 492 nm with the absorbance at 260 nm using NanoDrop ND1000 Microarray software (version 3.5.2). The efficiency of labeling obtained was approximately two labeled uridines per one RNA molecule.

RNA FD20H, used for the microscopy, contains 13 uridine residues (see Fig. 2): one at the end of F-stem region, three in the loops, and nine in the anti-replicative part of the molecule, which is not responsible for the mitochondrial import efficiency. Therefore, the labeling should not significantly alter the secondary structure and mitochondrial import of the RNA molecule.

Transient Transfection of Cybrid Cells—Trans-mitochondrial cybrid cell lines obtained by fusion of fibroblast-derived cytoplast from patient and a 143B rho0 cell line (19) were kindly provided by M. Zeviani (National Neurological Institute “Carlo Besta,” Milan, Italy).

Primary skin fibroblasts were from patient 1: a boy born to non-consanguineous healthy parents. He was completely normal until 13 years of age when he developed dystonia of the left hand that worsened progressively. A brain MRI at 14 years of age revealed hypersignal of basal ganglia and abnormalities of brain system consistent with the diagnosis of Leigh syndrome. Two years later, he had tonicoclonic seizures with nystagmus and dysarthria. Stroke-like pattern was detected by brain MRI. Measurement of respiratory chain activities detected an isolated complex I deficiency related to a mitochondrial DNA mutation in the ND5 gene (A13514G). Fibroblasts were characterized by a 30% heteroplasm level. Cells were cultivated at 37 °C and 5% CO2 in DMEM (Sigma) containing 4.5 g/liter of glucose supplemented with fetal calf serum (Invitrogen), penicillin/streptomycin, uridine (50 mg/liter), and fungizone (2.50 mg/liter) (Invitrogen).

Transient transfection of cells with RNA and chimeric molecules was performed as described in Refs. 20 and 21 with some modifications: for 2 cm2 well of 80% confluent cells, we used 0.25 μg of RNA and 1 μl of Lipofectamine 2000 in OptiMEM medium (Invitrogen). OptiMEM was changed to a standard DMEM medium 8 h after transfection. In these conditions, ~80% of fibroblasts and 95% of cybrid cells were transfected with RNA (evaluated by fluorescent microscopy and by flow cytometry using CyFlow FACS 24 h post transfection). We also compared Northern hybridization signals obtained on total cellular RNA and on the known amounts of T7 transcripts loaded on the same gel. We could estimate that ~15% of RNA added to cybrid cells and 20% RNA for fibroblasts were internalized and can be detected in full-size form 24 h post transfection (data not shown). Transfection procedure did not lead to detectable decrease of viability of the cells or to a significant change of the overall mtDNA amount verified by real-time quantitative PCR as described (15).

RNA Stability and Mitochondrial Import in Vivo—Mitochondria were isolated from the cybrid cells as described previously (22, 23) and treated with digitonin to generate mitoplasts (mitochondria devoid of the outer membrane) and RNase A to get rid of non-specifically attached RNA. This treatment allows us to obtain mitochondria free of cytosolic RNA contamination, which was tested using a probe for cytosolic 5.8 S rRNA usually strongly attached to the outer mitochondrial membrane. Total and mitochondrial RNA was isolated with TRIzol reagent (Invitrogen). Stability and mitochondrial import of recombinant molecules were analyzed by Northern hybridization of total and mitochondrial RNA with 32P-labeled oligonucleotide probes followed by PhosphorImager quantification (Typhoon Trio, GE Healthcare).

The probes used were as follows: “d-loop” probe-specific for recombinant molecules (see Fig. 1), 5’-GAG TCA TAC GCG CTA CCG ATT GCG CCA ACA AGG C-3’, hybridization temperature of 50 °C; cytosolic 5.8S rRNA probe, 5’-GGC CGC AAG TGC GTT CGA AG-3’, hybridization temperature of 50 °C; probe against the mitochondrial tRNAValVal, 5’-GAA CTT CGT ACT GTA AAG-3’, hybridization temperature of 45 °C; probe against the nuclear snRNA U3, 5’-CGC TAC CTC TCT TCC TCG TGG-3’, hybridization temperature of 50 °C. To compare the stability of different recombinant RNA, the relative concentration of each RNA in various time periods after transfection was calculated as a ratio between the d-loop probe signal and the signal for cytosolic 5.8 S rRNA.

The relative amount of each imported RNA inside the mitochondria was estimated as a ratio between the signal obtained after hybridization with the d-loop probe and the signal with a probe against the mitochondrial tRNAValVal in the same RNA preparation. To compare import efficiencies of different RNA molecules, the total level of each RNA molecule in transfected cells was taken into account and normalized as described previously (22). At least three independent experiments were performed for each RNA.

Confocal Microscopy—Cybrids cells cultivated in 2-cm2 chamber slides (Lab-Tek) were transfected with Alexa Fluor 488-5-UTP-labeled RNA. At different time periods after transfections, living cells were stained with 5 μM tetramethylrhodamine methyl ester (TMRM) for 15 min at 37 °C, washed, and imaged in DMEM without red phenol. The LSM 700 confocal microscope (Zeiss) was used in conjunction with Zen imaging software, and images were acquired with a Zeiss 63×/1.40 oil immersion objective with a resolution of 1024 × 1024. The excitation/emission laser wavelengths were 488 nm (green channel) and 555 nm (red channel). Images were analyzed using Image software (24) and JACoP plugin (25). Co-localization analyses were performed on multiple cells and optical sections. Pearson’s and Manders’ coefficients were estimated (26, 27). Pearson’s correlation coefficient provides a measure of correlation between the intensities of each channel in each pixel. The overlap coefficients according to Manders indicate an actual overlap of the signals and represent the true degree of co-localization. In control experiments, cells were transfected with
Mitochondrial Import of RNA as a Therapeutic Tool

Alexa Fluor 488-5-UTP-labeled RNA, which is not imported into mitochondria (28).

mtDNA Heteroplasmy Level Analysis—To isolate total DNA from transfected cells, 1 cm² of cells were solubilized in 0.5 ml of buffer containing 10 mM Tris-HCl, pH 7.5, 10 mM NaCl, 25 mM Na-EDTA, and 1% SDS, then 10 µl of proteinase K solution (20 mg/ml) was added, and the mixture was incubated for 2 h at 50 °C; 50 µl of 5 M NaCl was added, the DNA was precipitated with isopropanol alcohol and used for PCR amplification. Heteroplasmy level was analyzed by restriction fragment length polymorphism on a 125-bp PCR fragment encompassing nucleotides 13430 to 13555 of mtDNA obtained with primers CRS-F (5’-CGA TTT TCA TCT TTC CC-3’) and CRS-R (5’-AGG CTG TTT TGT ATG ATA TGT TGT C-3’) (19). The A13514G mutation creates a HaeIII-specific cleavage site, giving two fragments of 80 and 45 bp. The HaeIII-digested fragments were separated on a 10% PAGE and stained with ethidium bromide. The proportion of mutant versus total mtDNA was calculated by densitometry using G-Box and GeneTools analysis software (Syngene). At least four independent transfactions were performed with each recombinant RNA. Each DNA sample was analyzed twice by PCR amplification followed by at least three gel separation and quantification experiments.

The digestion control was performed for each reaction. For this, a 600-bp PCR fragment encompassing nucleotides 1216 to 1813 of mtDNA obtained with the primers CRS-F (5’-CGA TAA ACC CCG ATC AAC CTC C-3’) and CRS-R (5’-AGG CTG TTT TGT ATG ATA TGT TGT C-3’) (19). The A13514G mutation creates a HaeIII-specific cleavage site, giving two fragments of 80 and 45 bp. The HaeIII-digested fragments were separated on a 10% PAGE and stained with ethidium bromide. The proportion of mutant versus total mtDNA was calculated by densitometry using G-Box and GeneTools analysis software (Syngene). At least four independent transfactions were performed with each recombinant RNA. Each DNA sample was analyzed twice by PCR amplification followed by at least three gel separation and quantification experiments.

Mitochondria Quantification—2-cm² wells of 80% confluent cybrid cells and control wild type 143B cells, transfected with FD20H RNA, were stained with 5 µM MitoTracker® Green during 15 min in culture medium. The intensity of fluorescence was directly measured in a culture plate in DMEM without red phenol by VICTOR™ X3 multiplate reader (PerkinElmer Life Science) at 485 nm (green channel) and 555 nm (red channel) in triplicate for each sample. After fluorescence measurement, cells were detached and quantified by flow cytometry using CyFlow FACs and FloMax software (Partec). Activity of complex I was measured using a MitoSciences® kit (Abcam).

Statistical Analyses—Pairwise comparisons were performed using two-tailed Student’s t test and Excel software (Microsoft). Data are expressed as means ± S.D.

RESULTS

Design of Anti-replicative RNA Molecules—As it was reported previously, the helix-loop domains of FD RNA can serve as signals for RNA mitochondrial import, and this molecule can be used as a vector to deliver various sequences into the organelles (15). Recently, we also demonstrated that only one d-arm structure can be sufficient for targeting of recombinant molecule to mitochondria in living cells (28, 29).

To apply the anti-genomic strategy to point mutations, we used as a model the A13514G mutation inducing amino acid replacement D393G in the ND5 gene of human mtDNA, which encodes one of the membrane domain subunits of the respiratory complex I (30). This mutation was initially found in two unrelated patients with MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes)-like syndrome (19). To target the mutant mitochondrial genome, a series of RNA molecules were constructed, bearing sequences complementary to a mutated region of ND5 gene inserted between two helix-loop domains of a short artificial FD RNA (Fig. 1).

First, we analyzed the secondary structure predictions for FD RNA molecules bearing insertions of 16, 20, and 25 nucleotides corresponding to a fragment of the ND5 gene, referred to as FD16L, FD16H, FD20L, FD20H, FD25L, and FD25H; R for sequence of H-strand and S for L-strand of mtDNA. For each sequence, a series of insertions bearing nucleotide G or C corresponding to the mutation A13514G (for either H- or L-strand) in various positions (Fig. 1) were analyzed by several types of software (see “Experimental Procedures”) with similar results. Only molecules with a low probability of alternative folding were retained for further studies (Fig. 1). To check the ability of the selected versions for a specific annealing with mutated, but not wild type mtDNA, labeled recombinant RNAs were hybridized under physiological conditions with PCR-amplified mtDNA fragments either containing the mutation or not (Fig. 2). Versions FD25L and FD25H were not able to discriminate between mutant and wild type mtDNA; the shorter RNA molecule FD20H (but not FD20L) demonstrated specific annealing with the A13514G bearing mtDNA but not wild type. Annealing of molecules FD16H and FD16L was rather specific for mutant mtDNA; however, the efficiency of their hybridization at 37 °C was reproducibly lower when compared with FD20H. We also tested chimeric molecules, containing a stem-loop RNA import determinant and DNA inserts corresponding to FD20H and FD20L sequences, referred to as D20H-DNA and D20L-DNA (Fig. 2). Chimeric RNA-DNA molecule D20L-DNA demonstrated a higher ability to discriminate between mutant and wild type mtDNA when compared with FD20L. Thus, the recombinant molecules with 20 nucleotide insertions (FD20L, FD20H, D20L-DNA, and D20H-DNA) have been selected for the further analysis.

Mitochondrial Import of Recombinant RNA—To study the localization of recombinant RNA molecules in cultured human cells, an approach was developed consisting in cell transfection with Alexa Fluor 488-labeled RNA FD20H and its subsequent co-localization with the mitochondrial network by means of fluorescent confocal microscopy (Fig. 3). RNA molecules (green fluorescence) were detectable in cells in 24 h after transfection (day 1) as green dots, most probably representing the RNA-Lipofectamine complexes, with only slight co-localization with the mitochondria (red fluorescence). In 2–4 days after transfection, the distribution of the green label changed drastically, the amount of dots was reduced, and RNA molecules were now mostly dispersed within the cell, displaying clear partial co-localization with the mitochondrial network (Fig. 3B and supplemental movies). To perform quantitative co-localization analysis of confocal microscopy images, we estimated the values of Pearson’s correlation coefficient and Manders’ overlap coefficients M1 and M2 (26). For control RNA that is not imported into mitochondria (28), all of the coefficient values were very low (Fig. 3A), thus excluding the coincidental overlap
of green and red signals. For FD20H RNA, the M1 values indicated that in 2 days post transfection, ~50% of green fluorescence (RNA) has been co-localized with red fluorescence (mitochondria), and this level did not significantly change between 2 and 4 days post transfection. M2 values representing the percentage of the red fluorescence (mitochondria) overlap-

Recombinant RNA
ping with the green fluorescence (RNA) indicate that only 10% of mitochondria contained RNA in 2 days post transfection. This proportion has been increased in 3 and 4 days up to 70%, probably due to the mitochondrial dynamic events, fusion and fission, resulting in more homogenous RNA distribution. These data clearly indicate on mitochondrial targeting of FD20H RNA in living human cells.

To measure recombinant RNA stability in cultured cells and the efficiency of their import into the mitochondrial matrix, cybrid cells were transfected with in vitro-synthesized recombinant RNAs and chimeric molecules. Their degradation rate in transfected cells was evaluated by Northern hybridization of total cellular RNA at different time points spanning a 6-day period after transfection (Fig. 4A). Recombinant molecules were detectable in cybrid cells at least 6 days after transfection. The chimeric version D20L DNA revealed to be more stable than FD20L and FD20H. Such result suggests that the “insertion” part, lacking strong secondary structures, gives a prominent impact on the degradation of recombinant molecules. Thus, recombinant molecules in which RNA insertions were replaced by DNA sequences demonstrated improved stability in the living cells.

Because the microscopy data can give only a rough indication on the mitochondrial import of RNA molecules, we performed

FIGURE 2. Ability of recombinant molecules to discriminate wild type and mutant mtDNA. A, predicted secondary structures of anti-replicative molecules. Stem-loop import determinants are shown in gray. D20H DNA and D20L DNA, chemically synthesized chimeric molecules, RNA insertion has been replaced by DNA. B, Southern hybridization of WT or mutant (A13514G) mtDNA fragments with labeled recombinant RNAs (indicated at the left) under physiological conditions. Long exp., radiogram after longer exposition for FD16H and FD16L. The specific radioactivity of all of the RNA probes was comparable. C, graphical representation of hybridization specificity of different recombinant molecules (indicated below the graphs). The hybridization specificity was calculated for each RNA as 1 – (ratio between hybridization signals for wild type and mutated DNA fragments). Thus, for recombinant RNA annealed only to the mutant DNA fragment, the hybridization specificity value reached 1, and for RNA annealed equally to mutant and wild type fragments, this value was close to 0. Data are ± S.D. calculated from three independent experiments.
Northern blot hybridization experiments. For this, cells were transfected with purified recombinant molecules. The mitochondrial import was analyzed by hybridization of the whole cell RNA and RNA isolated from purified and RNase-treated mitoplasts (mitochondria where the outer membrane was removed by digitonin) as described previously (15, 22, 29). The absence of signal in the mitochondrial RNA preparation after hybridization with the probe against the cytoplasmic 5.8 S rRNA indicates that the treatment of mitochondria with ribonuclease and digitonin removed all contamination by cytosolic RNA (Fig. 4B). Hybridization signals obtained with the D-loop probe specific for all of the recombinant molecules were normalized to the amounts of loaded RNA, estimated by hybridization with a probe to a mitochondrial transcript (mito tRNAVal). The data show that the import efficiencies of RNA molecules FD20H and FD20L were close to each other; import of the chimeric molecule D20L-DNA was only slightly decreased (Fig. 4B).

Imported RNA Can Shift Point Mutation Heteroplasmy Level in Cybrid Cells—Trans-mitochondrial cybrid cell line containing a patient’s mitochondria with 35% of mtDNA molecules bearing an A13514G mutation (referred thereafter as ND5 mutation) were transfected with in vitro synthesized recombinant RNA and chimeric RNA-DNA molecules. Heteroplasmy levels (percentage of mutant ND5 mtDNA to all mtDNA molecules) were measured at different time points after transfection by restriction fragment length polymorphism analysis of
PCR-amplified mtDNA fragment (Fig. 5, A and B). We observed a reproducible decrease of the proportion of mutant mtDNA in cells transfected by recombinant RNA containing FD20H inserts. The heteroplasmy shift became visible 3 days after transfection, and then the heteroplasmy continued to decrease and reached the stable level of 13%/H110062% in 6 days post transfection. To affirm these data, we performed transfection of patient’s fibroblasts, harboring the A13514G mutation, with FD20H RNA (Fig. 5, A and B). This completely independent experiment on primary human cells gave the same result of heteroplasmy shift, as obtained on the cybrid cells model.

Remarkably, in cells transfected with FD20H RNA, the decrease of mutant mtDNA correlated to increased amount of mitochondria per cell measured as MitoTracker Green fluorescence (Fig. 5C). Moreover, the same increase of the fluorescence was detected by TMRM dye that is readily sequestered by active mitochondria, indicating on a fully energized state of mitochondrial membranes (31).

In parallel experiments, mock-transfected cybrid cells demonstrated no heteroplasy shift (Fig. 5, A and B). Cell transfection with FD20L RNA led to a very small heteroplasmy decrease, reaching the level of 27 ± 5% in 7 days (Fig. 5A). Different effects of FD20H and FD20L RNA molecules are in perfect correlation with the more specific hybridization of FD20H RNA with mutant mtDNA (Fig. 2). Surprisingly, chimeric molecule D20L DNA, characterized by a rather specific hybridization with mutant mtDNA in vitro, high stability in cells, and efficient import into mitochondria, was not able to influence the heteroplasmy level. Our data show that mitochondrially imported RNA (but not DNA) molecules can function as anti-genomic agents in human cells, affecting the amount of mitochondrial genomes bearing a point mutation.

**DISCUSSION**

Specific Annealing of RNA to mtDNA Bearing a Point Mutation—The anti-replicative approach aiming to shift heteroplasmy levels in mtDNA below the pathogenic threshold has been recently applied to cells containing a large 7-kb deletion in mtDNA (15). In this case, a new sequence generated at the fusion of the deletion boundaries has been inserted into RNA vector molecules, and specific annealing only with the mutant but not with wild type mtDNA was demonstrated for recombi-
Mitochondrial Import of RNA as a Therapeutic Tool

Table 1: Melting temperature predictions for hybrids between recombinant RNAs and mutated or WT mtDNA regions

| RNA     | Insert (bp) | $T_m$ for mutated DNA | $T_m$ for WT DNA | $\Delta T_m$ |
|---------|-------------|-----------------------|------------------|--------------|
| FD16L   | 16          | 48.4 °C               | 40.2 °C          | 8.2 °C       |
| FD16H   | 16          | 48.4 °C               | 35.0 °C          | 13.4 °C      |

$\Delta T_m$ are shown as values predicted by IDT Sci-Tools OligoAnalyser software (version 3.1). For mismatch containing DNA-DNA hybrids, $\Delta T_m$ predicted decrease of $T_m$ for wild type mtDNA compared with mutated mtDNA.

More recently, among the patients with Leigh-like syndrome and D393N mutation in ND5, several cases were reported characterized by normal complex I activity in muscle (36, 39). The authors suggested that the relatively low mutant heteroplasmy and normal respiratory chain activities in muscle do not necessarily represent the situation in affected tissue such as brain and/or optic nerve. Thus, even low mutation load in Asp-393 in the presence of normal respiratory chain analysis may be considered as pathogenic (36), illustrating the complexities of correlating A13514G heteroplasmy levels with biochemical phenotype in patient’s muscle and fibroblasts. This can be a characteristic feature of NADH dehydrogenase complex because it was recently demonstrated that even a low dose of wild type ND6 gene is sufficient to drive assembly of near normal levels of complex I (6). All of these data taken together indicate that a low load of mutation A13514G might cause a functional defect of ND5 protein, but this defect would be very low and hardly noticeable. This is exactly the case of cells used in the present study.

**Effect of Imported RNAs on mtDNA Heteroplasmy**—As we have shown previously, mitochondrially imported anti-replicative RNAs can cause a replication stalling at the site of RNA annealing to the mutant mtDNA because of slowdown of the
replication fork progression (15). Nevertheless, we obtained only a transient shift of heteroplasmy in cells bearing a large deletion in mtDNA, the initial heteroplasmy level being restored in 6–8 days after cell transfection with anti-replicative RNA. This can be explained by recombinant RNA degradation, followed by preferential replication of shorter mitochondrial genomes bearing deletion, due to the previously reported effect of “replicative advantage of deleted mtDNA” (40). In the present study, we successfully obtained a stable decrease of the proportion of mtDNA molecules containing ND5 point mutation after transfection of cybrid cells and primary fibroblasts with anti-replicative RNA FD20H (Fig. 5). Because no difference was expected in the rate of replication for wild type and mutant mtDNA, we can suggest that even after degradation of recombinant RNA, the induced shift in ND5 point mutation heteroplasmy level may become stable. The maintenance of wild type mtDNA enrichment was previously reported for several mutations (41, 42).

Among several anti-replicative recombinant molecules, characterized by comparable stability in cells and mitochondrial import efficiency (Fig. 4), only FD20H was able to induce a prominent heteroplasmy shift. This RNA molecule demonstrated the highest ability to discriminate between mutant and wild type mtDNA (Fig. 2). The chimeric molecule, containing the same sequence of the insertion part as FD20H, but in the form of DNA, was not capable to shift the heteroplasmy level (Fig. 5). These data provide an additional proof of recombinant RNA action at the level of mtDNA replication because it was suggested that mitochondrial replisome helicase can separate DNA-DNA hybrids but not regions of short RNA-DNA hybrids in the mtDNA p-loop (43). Thus, only mitochondrially imported RNA (but not DNA) molecules are likely to function as anti-replicative agents in human mitochondria.

Cybrid cells used in the present study, containing 35% of mtDNA molecules bearing the A13514G mutation, were almost asymptomatic, characterized by a very slight decrease of all of the measurable parameters as oxygen consumption, levels of ATP, reactive oxygen species, and complex I enzymatic activity compared with wild type 143B cell line (data not shown). Nevertheless, we observed a prominent decrease of amount of mitochondria in cybrid cells, measured by use of MitoTracker Green, a mitochondria-selective fluorescent label, accumulating in the matrix (Fig. 5C) (44). Notably, transfection with anti-replicative RNA FD20H, leading to an important decrease of the level of ND5 point mutation, caused, at the same time, a recovery of mitochondrial content. Unexpectedly, if the MitoTracker Green fluorescence increased gradually from day 4 to day 6 post transfection and then reached a plateau, the shift of the TMRM fluorescence between days 4 and 5 was rather sharp. Thus, we observe some temporary hyperpolarization of mitochondria only at day 5 post transfection. We can hypothesize that following the heteroplasmy decrease observed for ND5 cybrid cells in 3–4 days post transfection, the synthesis of increased amounts of normal, fully active ND5 protein might create a temporary unbalance in the assembly of respiratory complexes, resulting in a rise of the basal production of reactive oxygen species (at the 5th day) and increasing mitochondrial biogenesis (days 6–8).

All of our data indicate on the possibility to obtain a curative effect of mitochondrial dysfunctions in human cells by a heteroplasmy shift induced by short RNA molecules targeted into mitochondria. Although the inhibitory effect was partial, it may have a long term therapeutic interest because only high levels of mutations in human mtDNA become pathogenic. The validation of the anti-replicative RNA strategy for a point mutation in mtDNA in cultured human cells can be considered as an important step to further develop an efficient therapy of mitochondrial diseases.

Acknowledgments—We are grateful to Massimo Zeviani (National Neurological Institute “Carlo Besta” of Milan) for providing the trans-mitochondrial cybrid cell lines and to Jérôme Mutterer (Institute of Molecular Biology of Plants, Strasbourg) for helpful assistance in confocal microscopy analysis. We also thank Virginie Girault, Catherine Murfitt, Laure Poirier, and Charlotte Simonin for experimental contributions.
