Insecticide-treated nets and malaria prevalence, Papua New Guinea, 2008–2014

Manuel W. Hetzel,1 Justin Pulford,2 Yangta Ura,3 Sharon Jamea-Maisa,2 Anthony Tandrapah,6 Nandao Tarongka,2 Lina Lorry,7 Leanne J. Robinson,5 Ken Lilley,2 Leo Makita,2 Peter M. Siba5 & Ivo Mueller2

Objective To investigate changes in malaria prevalence in Papua New Guinea after the distribution of long-lasting Insecticide-treated nets, starting in 2004, and the introduction of artemisinin-based combination therapy in 2011.

Methods Two malaria surveys were conducted in 2010–2011 and 2013–2014. They included 77 and 92 randomly selected villages, respectively. In each village, all members of 30 randomly selected households gave blood samples and were assessed for malaria infection by light microscopy. In addition, data were obtained from a malaria survey performed in 2008–2009.

Results The prevalence of malaria below 1600 m in altitude decreased from 11.1% (95% confidence interval, CI: 8.5–14.3) in 2008–2009 to 5.1% (95% CI 3.6–7.4) in 2010–2011 and 0.9% (95% CI 0.6–1.5) in 2013–2014. Prevalence decreased with altitude. Plasmodium falciparum was more common than P. vivax overall, but not everywhere, and initially the prevalence of P. vivax infection decreased more slowly than P. falciparum infection. Malaria infections were clustered in households. In contrast to findings in 2008–2009, no significant association between net use and prevalence was found in the later two surveys. The prevalence of both fever and splenomegaly also decreased but their association with malaria infection became stronger.

Conclusion Large-scale insecticide-treated net distribution was associated with an unprecedented decline in malaria prevalence throughout Papua New Guinea, including epidemic-prone highland areas. The decline was accompanied by broader health benefits, such as decreased morbidity. Better clinical management of nonmalarial fever and research into residual malaria transmission are required.

Introduction

Historically, malaria has been endemic throughout Papua New Guinea, except in highland areas over 1600 m, where temperatures are low and there is no stable local transmission, though imported cases and epidemics do occur.1–3 The causative parasites Plasmodium falciparum, Plasmodium vivax, Plasmodium malariae and Plasmodium ovale are transmitted by various Anopheles mosquito species adapted to distinct ecological niches.4 The epidemiology of malaria in the country and, consequently, its control are complex due to the number of parasite and mosquito species present, the variety of mosquito behaviour, the diversity of the natural environment and operational difficulties.

Since 2004, the country’s national malaria control programme has been supported by the Global Fund to Fight AIDS, Tuberculosis and Malaria. National campaigns were organized to distribute free, long-lasting insecticide-treated nets at the household level and, since late 2011, malaria rapid diagnostics tests, improved diagnostic microscopy and artemisinin-based combination therapy have increasingly been provided at public and church-run health-care facilities.5,6

In 2008–2009, towards the end of the first insecticide-treated net campaign, the Papua New Guinea Institute of Medical Research conducted a country-wide malaria indicator survey. It documented that 65% of households in areas covered by the campaign owned long-lasting insecticide-treated nets and that 33% of people were using them.1 In addition, malaria was found to be widespread, with a heterogeneous prevalence.7 Light microscopy diagnosis indicated that P. falciparum was the most common species, followed by P. vivax, which dominated in several locations. A few P. malariae infections were found but P. ovale was not detected in any sample. Within 1 year of the initial insecticide-treated net campaign, a significant reduction in the prevalence, incidence and transmission of malaria was documented at selected sites, even though insect vectors tended to feed outdoors.8 However, entomological investigations indicated that biting patterns and changes in these patterns may reduce the impact of vector control.9

Subsequent national malaria surveys conducted by the Papua New Guinean Institute of Medical Research in 2010–2011 and 2013–2014 to evaluate the national malaria control programme provided evidence that coverage with long-lasting insecticide-treated nets had increased.5,10 Here, we present data on malaria prevalence from these follow-up surveys and analyse changes relative to the baseline survey of 2008–2009.

Methods

National malaria surveys were conducted from November 2010 to August 2011 and from November 2013 to August 2014. In both surveys, five villages were randomly selected from each of the country’s 20 provinces – organized in four regions – using a list of villages identified in the 2000 nationalfortune.
census – the most up-to-date.¹¹ Not all provinces or selected villages could be included because of problems with access and security. The pre-2012 province structure was adopted to ensure comparability over time: Hela Province was considered part of Southern Highlands Province and Jiwaka Province, part of Western Highlands Province. For each village, the survey team leader selected a random sample of 30 households using a list compiled by village leaders. All members of sampled households were eligible for inclusion. The sample size, which took into account financial and operational constraints, was adequate for detecting a 25% reduction in parasitaemia from 2008–2009 to 2010–2011 at the regional level at a 95% level of significance with 80% power. The first survey in 2008–2009, whose results are presented for comparison, included villages from only districts covered by the long-lasting insecticide-treated net campaign, but the method of selecting households and their members was identical to that in subsequent surveys.⁷

Data were collected using an adapted Malaria Indicator Survey questionnaire.¹² Household heads provided details of each household member’s demographic characteristics and coverage by malaria interventions. A capillary blood sample was collected by fingerstick from each available, consenting household member aged over 5 months. Trained study nurses prepared one thick and one thin blood film for light microscopy. The haemoglobin concentration was measured using a portable HemoCue Hb 201⁺ photometric analyser (HemoCue AB, Angelholm, Sweden). Symptomatic household members were offered a malaria rapid diagnostic test and treatment or referral to the nearest health-care facility, where appropriate.

Axillary temperature was measured using an electronic thermometer and children aged between 2 and 9 years had their spleen palpated. Each patient’s blood sample was accompanied by information on recent travel. The locations of the survey villages were determined using a hand-held Garmin eTrex Global Positioning System device (Garmin Ltd., Olathe, United States of America).

Malaria was diagnosed by light microscopy at the Papua New Guinean Institute of Medical Research following established procedures.³⁷ Each slide was examined independently by two microscopists, each viewing a minimum of 200 thick film fields. Slides with discordant results were examined by a third microscopist, who was certified at World Health Organization (WHO) level 1 or 2. A slide was considered positive for malaria if judged positive by at least two microscopists. For the 2010–2011 survey, additional assessments of unclear species identifications were performed at the Australian Army Malaria Institute in Australia by WHO-certified level-1 malaria microscopists.

The number of parasites per 200 white blood cells was determined. The study was approved by the Papua New Guinea Medical Research Advisory Committee (MRAC no. 07.30 and no. 10.12).

### Table 1. National malaria surveys, Papua New Guinea, 2010–2014

| Region and province | 2010–2011 survey | 2013–2014 survey |
|---------------------|------------------|------------------|
|                     | Villages¹ | Individuals tested | Villages¹ | Individuals tested |

¹ For security and operational reasons, 23 villages could not be surveyed in 2010 to 2011 and 10 could not be surveyed in 2013 to 2014.

ND: not determined.
Data analysis

Measures of the prevalence of malaria infection and morbidity were age-standardized using the standard population for Asia given by the International Network for the Demographic Evaluation of Populations and Their Health (INDEPTH). Results are presented separately for villages below 1600 m in altitude and include comparisons with data from the 2008–2009 survey. For villages at 1600 m or higher, we compared data from the 2010–2011 and 2013–2014 surveys only as the 2008–2009 survey included few highland villages. To account for stratified sampling, national estimates were weighted, as described elsewhere. Splenomegaly was defined as a palpable spleen (i.e. Hackett grade 1 to 5) and anaemia was defined according to WHO recommendations, which include age-specific cut-offs and altitude corrections. Living in a high-quality house served as a proxy for having both good sanitation and a relatively high socioeconomic status, as defined elsewhere. Binary variables were compared using \( \chi^2 \) tests and logistic regression, and non-normally distributed variables were compared using the non-parametric Mann–Whitney U test. Data analyses were conducted using Stata/IC v. 14.0 (StataCorp LP, College Station, USA) and the survey design was taken into account by using Statas set of commands for survey data analysis (svy).

Results

In the 2010–2011 survey, blood samples were collected from 10 060 individuals. Of the 77 villages included, 58 (75.3%) were below 1200 m in altitude, 5 (6.5%) were between 1200 and 1599 m and 14 (18.2%), with 1539 participants, were at 1600 m or higher (Table 1). In the 2013–2014 survey, blood samples were collected from 8408 individuals. Of the 92 villages included, 66 (71.7%) were below 1200 m, 4 (4.3%) were between 1200 and 1599 m and 22 (23.9%), with 1536 participants, were at 1600 m or higher (Table 1). The small number of villages at intermediate altitudes reflects the population distribution in Papua New Guinea. The age distribution of survey participants is shown in Table 2. In the 2010–2011 survey, the participants’ median age was 19 years (interquartile range, IQR: 8–36): 14.1% (1418/10 060) were aged under 5 years.

Table 2. Age of participants, national malaria surveys, Papua New Guinea, 2010–2014

| Age, years | 2010–2011 survey | 2013–2014 survey |
|------------|------------------|------------------|
| No. (%)    | No. (%)          |                  |
| < 1        | 72 (0.7)         | 95 (1.1)         |

Note: Error bars represent 95% confidence intervals.

Fig. 1. Age-standardized prevalence of Plasmodium infection and insecticide-treated net use, by region and survey date, national malaria surveys, Papua New Guinea, 2008–2014

P. falciparum: Plasmodium falciparum; P. vivax: Plasmodium vivax.

Note: Error bars represent 95% confidence intervals.
and 52.8% (5290/10 028) were female. In the 2013–2014 survey, the comparable figures were 22 years (IQR: 9–38), 11.7% (985/8408) and 52.3% (4363/8348), respectively.

**Malaria prevalence**

Nationally, in villages below 1600 m in altitude, the age-standardized prevalence of malaria, as diagnosed by light microscopy, decreased significantly from 11.1% (95% confidence interval, CI: 8.5–14.3) in 2008–2009 to 5.1% (95% CI: 3.6–7.4) in 2010–2011 (P < 0.001) and to 0.9% (95% CI: 0.6–1.5) in 2013–2014 (P < 0.001). The prevalence of *P. falciparum* infection was higher than that of *P. vivax* infection in all surveys (Table 3). There was no evidence of *P. ovale* infection in any sample. For individual *Plasmodium* species, the difference in infection prevalence between subsequent surveys was significant at a P-value ≤ 0.001 for all comparisons except for *P. malariae* infection, for which the P-value for the difference between subsequent surveys was < 0.05, and for mixed *P. falciparum* and *P. vivax* infection between the 2008–2009 and 2010–2011 surveys, where the decrease was not significant.

Between the 2008–2009 and 2010–2011 surveys, an increase in the prevalence of *P. vivax* infection was noted in two of the country’s four regions (Fig. 1) and in several provinces (Fig. 2 and Fig. 3), which led to a decrease in the ratio of *P. falciparum* to *P. vivax* infection. However, the prevalence of infection by both species decreased in all provinces between 2010–2011 and 2013–2014. In 2013–2014, no parasites were detected in any sample from 11 of the 19 provinces surveyed (Table 4; available at: http://www.who.int/bulletin/volumes/94/10/16-189902).

**Fig 2.** Age-standardized prevalence of *Plasmodium* infection and insecticide-treated net use in lower-prevalence areas, by province and survey date, national malaria surveys, Papua New Guinea, 2008–2014

---

*P. falciparum*: *Plasmodium falciparum*; *P. vivax*: *Plasmodium vivax*.
In highland villages at 1600 m and above, the age-standardized prevalence of malaria decreased from 0.7% (95% CI: 0.3–1.2) in 2010–2011 to 0.1% (95% CI: 0–0.7) in 2013–2014 (P = 0.004). In the 2010–2011 survey, the prevalence of *P. falciparum* infection was higher than that of *P. vivax* infection in highland villages: 0.6% (95% CI: 0.3–1.1) and 0.1% (95% CI: 0–0.7), respectively. In the 2013–2014 survey, the prevalence of *P. falciparum* infection was 0.1% (95% CI: 0–0.4), whereas no *P. vivax* infections were detected. Moreover, no *P. malariae*, *P. ovale* or mixed infections were found.

**Predictors of infection**

Regression analysis findings are presented in Table 5. Univariable logistic regression found that, in 2010–2011, malaria infection was significantly less likely above 1600 m (odds ratio, OR: 0.15; 95% CI: 0.06–0.38); in 2013–2014, the corresponding OR was 0.04 (95% CI: 0.00–0.33). The prevalence of infection below 1600 m was significantly

| Table 5. Factors associated with malaria infection, national malaria surveys, Papua New Guinea, 2010–2014 |
|-----------------------------------------------|-------------------------------------------------|-------------------------------------------------|
| Risk factor | Risk of malaria infection | Univariable logistic regression analysis | Multivariable logistic regression analysis |
|-----------------------------------------------|-------------------------------------------------|-------------------------------------------------|
| 2010–2011 survey | Village at 1600 m or higher | 0.15 (0.06–0.38) | 0.16 (0.06–0.42) |
| Age < 5 years | 2.98 (2.40–3.71) | 2.59 (2.08–3.23) |
| Long-lasting insecticide-treated net use | 1.38 (1.00–1.90) | 1.09 (0.82–1.45) |
| High-quality house* | 0.30 (0.11–0.83) | 0.25 (0.08–0.79) |
| Percentage net use in village | 1.01 (1.00–1.02) | ND |
| 2013–2014 survey | Village at 1600 m or higher | 0.04 (0.00–0.33) | 0.04 (0.00–0.36) |
| Age < 5 years | 1.59 (0.74–3.44) | 1.47 (0.68–3.21) |
| Long-lasting insecticide-treated net use | 1.42 (0.83–2.45) | 1.08 (0.64–1.82) |
| High-quality house* | 1.00 | ND |
| Percentage net use in village | 1.01 (1.00–1.03) | ND |

aOR: adjusted odds ratio; CI: confidence interval; ND: not determined; OR: odds ratio.

* Living in a high-quality house served as a proxy for having both good sanitation and a relatively high socioeconomic status.
lower in older individuals in all years (Fig. 4): \( P < 0.001 \) for the 2008–2009 and 2010–2011 surveys and \( P = 0.03 \) for the 2013–2014 survey. For \( P. falciparum \) infection, the peak prevalence shifted to a younger age between 2008–2009 and 2010–2011, but there was no corresponding change for \( P. vivax \) infection (Fig. 5). In 2013–2014, the difference in the prevalence of \( P. falciparum \) and \( P. vivax \) infection between age groups was not significant. However, 62.7% (95% CI: 42.2–79.4) of \( P. vivax \) infections and 9.1% (95% CI: 3.4–22.0) of \( P. falciparum \) infections occurred in children aged under 5 years.

Long-lasting insecticide-treated nets were used by 32.5% (95% CI: 27.0–38.4) of the population nationally in 2008–2009, by 48.3% (95% CI: 41.8–54.9) in 2010–2011 and by 53.9% (95% CI: 49.4–58.4) in 2013–2014. In the 2008–2009 survey, a significant association was found between net use and a lower risk of malaria infection (adjusted odds ratio, aOR: 0.64; 95% CI: 0.54–0.76). However, no corresponding association was found in the 2010–2011 survey (aOR: 1.09; 95% CI: 0.82–1.45), in an analysis that adjusted for altitude, age and housing quality, or in the 2013–2014 survey (aOR: 1.08; 95% CI: 0.64–1.82), in an analysis that adjusted for altitude and age (Table 5). In 2010–2011, people living in high-quality houses were significantly less likely to be infected (aOR: 0.25; 95% CI: 0.08–0.79). Malaria cases were clustered in households. Univariable analysis found that, in 2010–2011, the odds of infection were over 26 times higher for individuals living with an infected person than for those who were not (OR: 25.65; 95% CI: 16.18–40.67); in 2013–2014, the odds were over 77 times higher (OR: 77.16; 95% CI: 41.61–143.09). In 2010–2011, 47% of malaria-infected individuals lived in a household with another infected person; in 2013–2014, the corresponding proportion was 25%.

**Morbidity**

In all surveys, individuals infected with malaria were significantly more likely than those without to report a recent fever episode, to show symptoms of acute fever (i.e. an axillary temperature over 37.5 °C), to be anaemic or, in those aged 2 to 9 years, to have splenomegaly (\( P < 0.01 \) for all). Although the proportion of the population with a recent
history of fever decreased over time (Fig. 6), the association between malaria infection and a recent history of fever became stronger, particularly after 2010: the OR adjusted for age was 2.05 (95% CI: 1.41–2.99) in 2008–2009, 2.57 (95% CI: 1.74–3.81) in 2010–2011 and 12.34 (95% CI: 4.56–33.33) in 2013–2014. In 2013–2014, 37.4% of all infected individuals reported a recent fever episode (Fig. 6) and 3.7% had an acute fever (Fig. 7). The prevalence of splenomegaly in participants aged 2 to 9 years also decreased over time (Fig. 8) and again the association with infection tended to become stronger: the OR adjusted for age was 4.72 (95% CI: 2.38–9.34) in 2008–2009, 10.0 (95% CI: 5.10–19.60) in 2010–2011 and 21.84 (95% CI: 5.52–88.46) in 2013–2014. The prevalence of anaemia remained high over time and increased between 2010–2011 and 2013–2014 (Fig. 9 and Fig. 10). Independent of the effect of malaria infection, in 2013–2014, anaemia was significantly associated with residing in a village below 1200 m in altitude (aOR: 8.63; 95% CI: 6.66–11.18), age under 5 years (aOR: 4.38; 95% CI: 2.96–6.46) and female sex (aOR: 1.54; 95% CI: 1.35–1.75).

Discussion

Within 5 years, the prevalence of malaria in Papua New Guinea decreased from 11.1% to 0.9% and during 2013–2014 no parasites were detected by light microscopy in most provinces. This is a greater reduction than the 26% observed in Africa between 2000 and 2016. Moreover, the prevalence in 2014 was lower than that in other countries in the Asia-Pacific region, including the neighbouring Papua province of Indonesia. An initial shift towards proportionally more *P. vivax* than *P. falciparum* infections appeared to be transient and was followed by a clear reduction in both species, as observed elsewhere. These trends are in line with previously documented declines in malaria following the introduction of long-lasting insecticide-treated nets. Provinces in which no malaria parasites were found should not be considered malaria-free because, as parasite density decreases, an increasing proportion of infections becomes sub-microscopic, particularly if transmission decreases faster than the loss of
immunity. In three provinces with zero prevalence, rapid diagnostic tests found that people with fever who had not left the province had a current or recent infection. Consequently, maintaining a high level of intervention coverage is crucial for avoiding resurgence. The notion that climatic change might have increased malaria in the highlands could not be substantiated. In locations above 1600 m, malaria prevalence was lower in 2010–2011 and 2013–2014 than between 2000 and 2005. The protective effect of insecticide-treated nets in both the highlands and lowlands, from where infections are often imported, may have outweighed the impact of changing weather patterns or increased people movement. Unlike in previous years, P. falciparum was the dominant species in the highlands.

The prevalence of fever and splenomegaly declined with that of parasite infection. However, the association between infection and symptoms became stronger over time, perhaps because the proportion of microscopically detectable infections that were symptomatic increased as transmission and immunity declined. The decrease in splenomegaly was most marked, which may reflect a reduction in chronic malaria infection. On the other hand, anaemia remained common, indicating that the cause is multifactorial. Anaemia may not, therefore, be useful for monitoring rapid changes in malaria prevalence. As severe anaemia, in particular, affects children’s health and development, its causes and appropriate mitigating measures should be investigated.

Between 2004 and 2012, the distribution of insecticide-treated nets to households was the only large-scale malaria intervention in Papua New Guinea. The baseline survey demonstrated a strong negative association between net coverage and malaria prevalence. In the absence of other factors, such as major economic developments or a prolonged drought, it is plausible that the drop in prevalence between the 2008–2009 and 2010–2011 surveys resulted from increased provision of nets and measures promoting their use. The lack of an association between net use and malaria prevalence in the last two surveys may have been due to factors such as outdoor biting, which sustained disease transmission, and the mass effect of net use on all community members. With our survey design, it was not possible to quantify the relative contributions of net use and artemisinin-based combination therapy to the reduction in prevalence. Combination therapy was introduced in November 2011 and, by late 2012, was available at approximately half of health-care facilities. Nevertheless, although the treatment’s gametocidal effect can reduce transmission from patients, its prophylactic effect is limited. Moreover, in 2014, only 45% of patients with confirmed or suspected malaria who attended health-care facilities were treated with artemisinin-based combination therapy, which corresponds to a population coverage of 19% at best. The community benefits of combination therapy can be maximized by prompt diagnosis and treatment. With decreasing malaria prevalence, clinicians across Papua New Guinea should be encouraged to administer antimalarials only to people with a positive test result, which has proven to be a safe approach, and to thoroughly investigate the causes of nonmalarial fevers. Better guidance on differential diagnosis and on fever management is warranted.

We found that individuals cohabiting with another infected person were more likely to carry parasites, possibly due to similar exposure patterns. There were fewer infections in high-quality houses occupied by better-off households, possibly because of economic factors or the building’s structure or location – most high-quality houses were in urban areas. Earlier studies in Papua New Guinea found conflicting evidence of the impact of housing, namely raised structures, on mosquito exposure. As indoor exposure to malaria vectors has been reduced by nets, people’s outdoor behaviour may be an increasingly important determinant of exposure as many vectors tend to bite outdoors. The investigation of residual malaria transmission is crucial for eliminating the disease and should take into account human and mosquito behaviour patterns, including the distribution of different Anopheles populations, their biting preferences and their susceptibility to interventions.

In our study, we used age-standardization to account for differences in the age-composition of participants between surveys and between participants who gave blood samples and the general population. However, as the 2008–2009 survey included only districts where nets were distributed, the national prevalence of parasite infection may have been underestimated. Data from sentinel sites showed that the prevalence after net distribution was 4.8% compared with 15.7% before. In addition, the estimated prevalence in the 2010–2011 and 2013–2014 surveys may have been too low because, due to security concerns, they excluded West New Britain Province, where the prevalence is traditionally high.

In conclusion, increased use of long-lasting insecticide-treated nets in Papua New Guinea was associated with a rapid and significant decline in malaria prevalence – the lowest prevalence ever recorded was in 2013–2014. The decline also occurred in the epidemic-prone highlands. Light microscopy showed that P. falciparum remained more common than P. vivax.
Declining prevalence was accompanied by broader health benefits, such as decreased morbidity. However, nonmalarial fever now requires better clinical management. Research into the drivers of residual malaria transmission and the burden and role of submicroscopic parasite infection are crucial for better targeting of interventions and for eliminating the disease.

Acknowledgements
We thank all participating individuals, communities and village leaders, government officials in the provinces and at the National Department of Health, all partners in the Malaria Technical Working Group, staff at the Papua New Guinean Institute of Medical Research and the Australian Army Malaria Institute and field data collectors and we remember the five team members who disappeared without trace in West New Britain province. MWH is affiliated with the Walter and Eliza Hall Institute, the University of Melbourne and the MacFarlane Burnet Institute of Medical Research, Australia and IM is affiliated with the University of Melbourne, Australia and the Institut Pasteur, France.

ملخص

الناموسيات المعالجة بالبيد الحشري وانتشار الملاريا في بابوا غينيا الجديدة في الفترة ما بين عامي 2008 و2014

الغرض: التحقيق في تغيرات انتشار الملاريا في بابوا غينيا الجديدة بعد توزيع الناموسيات المعالجة بالبيد الحشري ذات المفعول الممتد، بدءًا من عام 2004، وطرح العلاج المجمّع المرتكز على مادة الأرتيميسينين في عام 2011. الطريقة: أجريت دراستان استقصائيتان للملاريا في عامي 2011-2013 و 2014-2016. وشملتا 77 و 92 قرية تم اختيارها عشوائيًا. في كل قرية، تم أخذ عينات عشوائية من الدم وتقييمها بواسطة الفحص المجهري لمعرفة ما إذا كان هناك إصابة بالملاريا. بالإضافة إلى ذلك، تم الحصول على البيانات من مسح الملاريا الذي تم إجراؤه في الفترة ما بين عامي 2008-2009 و 2010-2011.

النتائج: انخفض معدل انتشار الملاريا في المناطق التي لا يزيد ارتفاعها عن 1600 متر (4.5 في الفترة ما بين عامي 2008-2009 و 2010-2011) إلى 0.9٪ (범위 0.6٪-0.7٪) في الفترة ما بين عامي 2010-2011.

الاستنتاج: ارتفاع معدل انتشار الملاريا في المناطق التي لا يزيد ارتفاعها عن 1600 متر (4.5 في الفترة ما بين عامي 2008-2009 و 2010-2011) إلى 0.9٪ (범위 0.6٪-0.7٪) في الفترة ما بين عامي 2010-2011.

Malaria in Papua New Guinea

Resumen

Moustiquaires imprégnées d’insecticides et prévalence du paludisme en Papouasie-Nouvelle-Guinée entre 2008 et 2014

Objetif Étudier les changements observés à l’égard de la prévalence du paludisme en Papouasie-Nouvelle-Guinée suite à la distribution, depuis 2004, de moustiquaires imprégnées d’insecticides de longue durée et à l’introduction, depuis 2011, d’une combinaison thérapeutique à base d’artémisinine.

Méthodes Deux enquêtes portant sur le paludisme ont été menées en 2010-2011 et 2013-2014. Elles incluaient respectivement 77 et 92 villages, sélectionnés d’une manière aléatoire. Dans chacun de ces villages, tous les membres de 30 foyers sélectionnés aléatoirement ont donné les échantillons sanguins et ont été soumis à un test de dépistage de l’infection palustre par microscopie optique. Des données ont par ailleurs été tirées d’une enquête sur le paludisme réalisée en 2008-2009.

Résultats La prévalence du paludisme à moins de 1600 m d’altitude est passée de 11,1% (intervalle de confiance, IC, à 95%: 8,5–14,3) en 2008–2009 à 5,1% (IC à 95%: 3,6–7,4) en 2010–2011 et 0,9% (IC à 95%: 0,6–1,5) en 2013–2014.

Conclusion La distribution à grande échelle de moustiquaires imprégnées d’insecticides a été associée à un déclin sans précédent de la prévalence du paludisme dans l’ensemble de la Papouasie-Nouvelle-Guinée, et notamment dans les régions montagneuses sujettes aux épidémies. Ce déclin s’est accompagné d’autres bénéfices sur la santé, et notamment d’une diminution de la morbidité.

Resumen

Mosquiteros tratados con insecticida y prevalencia de malaria, Papua — Nueva Guinea, 2008–2014

Objetivo Investigar los cambios en la prevalencia de la malaria en Papua Nueva Guinea tras la distribución de mosquiteros tratados con insecticida de larga duración, a partir de 2004, y la introducción de terapias combinadas basadas en la artesuminina en 2011.

Métodos Se llevaron a cabo dos encuestas sobre la malaria en 2010–2011 y 2013–2014. Incluyeron 77 y 92 aldeas seleccionadas al azar, respectivamente. En cada aldea, todos los miembros de 30 hogares seleccionados al azar dieron muestras de sangre y se evaluaron de infección de malaria con microscopio óptico. Además, se obtuvieron datos de la encuesta sobre la malaria realizada en 2008–2009.

Resultados La prevalencia de la malaria por debajo de 1600 m de altitud descendió del 11.1% (intervalo de confianza (IC) del 95%: 8.5–14.3) en 2008–2009 al 5.1% (IC del 95% IC 3.6–7.4) en 2010–2011 y 0.9% (IC del 95% IC 0.6–1.5) en 2013–2014. La prevalencia descendió con la altitud. Plasmodium falciparum fue más común que P. vivax en general, pero no en todas partes e inicialmente la prevalencia de la infección P. vivax descendió más lentamente que la infección P. falciparum. Las infecciones de malaria se agruparon en los hogares. Al contrario que los hallazgos en 2008–2009, en dos más pоздних исследованиях no hubo evidencia de que la infección de malaria se asociaba con el uso del mosquitero y la prevalencia en los hogares. Al contrario que los hallazgos en 2008–2009, en dos más pоздних исследованиях no hubo evidencia de que la infección de malaria se asociaba con el uso del mosquitero y la prevalencia en los hogares. Al contrario que los hallazgos en 2008–2009, en dos más pоздних исследованиях no hubo evidencia de que la infección de malaria se asociaba con el uso del mosquitero y la prevalencia en los hogares. Al contrario que los hallazgos en 2008–2009, en dos más pоздних исследованиях не было выявлено существенной взаимосвязи между использованием сеток и распространенностью инфекции. Распространенность как лихорадки, так и спленомегалии также снижалась, но их взаимосвязь с мальрией стала более явной.

Вывод Широкомасштабное распространение использования сеток, обработанных инсектицидами длительного действия, было связано с беспрецедентным снижением распространенности мальрии во всей Папуа — Новой Гвинее, включая районы, подверженные эпидемиям. Снижение распространенности инфекции сопровождалось более широкими преимуществами для здоровья, такими как снижение заболеваемости. Требуется введение более качественных клинических протоколов ведения и лечения лихорадки, не связанной с мальрией, а также проведение исследования оставшихся очагов распространения мальрии.

Conclusion La distribución de mosquiteros tratados con insecticida a gran escala se asocia con un descenso sin precedentes en la prevalencia de la malaria en toda Papua Nueva Guinea, incluidas las áreas altas con propensión a causar epidemias. El descenso estuvo acompañado de beneficios saludables más amplios, como el descenso de la morbilidad. Se requieren una mejor gestión clínica de la fiebre no relacionada con la malaria y la investigación de la transmisión residual de la malaria.
