Exact solutions and topological phase diagram in interacting dimerized Kitaev topological superconductors

Motohiko Ezawa

It was recently shown that an interacting Kitaev topological superconductor model is exactly solvable based on two-step Jordan-Wigner transformations together with one spin rotation. We generalize this model by including the dimerization, which is shown also to be exactly solvable. We analytically determine the topological phase diagram containing seven distinct phases. It is argued that the system is topological when a fermionic many-body Majorana zero-energy edge state emerges. It is intriguing that there are two tetra-critical points, at each of which four distinct phases touch.

**Introduction:** Majorana fermions were used for the first time in condensed matter physics to exactly solve the two-dimensional Ising model by mapping it to the one-dimensional quantum spin model with the use of the Jordan-Wigner transformation. Recently, a renewed interest on Majorana fermions has created one of the most active fields in the context of topological superconductors. The Kitaev topological superconductor (KTSC) model is a fundamental one which hosts Majorana fermions. It is exactly solvable since it describes free electrons. An interplay between topology and interaction is a fascinating subject. There are several works where electron-electron interaction effects have been investigated. It is shown that there is a topological phase transition between a topological superconductor (TSC) state and trivial charge-density wave (CDW) state at a certain interaction strength.

The KTSC model is characterized by the three parameters, i.e., the transfer integral $t$, the superconducting pairing gap $\Delta$ and the chemical potential $\mu$. The system is topological for $|\mu| < 2t$, while it is trivial for $|\mu| > 2t$. The interacting KTSC model contains an additional electron-electron interaction $U$. It is exactly solvable under the frustration free condition, i.e., $\mu = 4t\sqrt{U^2 + 4U^2 + (t^2 - \Delta^2)/4}$. It is also exactly solvable at the symmetric point $\Delta = U = t$ and $\mu = 0$. Recently, this exact solution is extended for $\Delta = t$ and $\mu = 0$ with an arbitrary $U$ by mapping the system to the KTSC model with the aid of the combination of two-step Jordan-Wigner transformations and one spin rotation. This method is also applicable to the KTSC model with disorders.

In this paper, we generalize the interacting KTSC model by including the dimerization with parameter $\eta$, $|\eta| \leq 1$. The model is exactly solvable for the case of $\Delta = t$ and $\mu = 0$ with an arbitrary $U$. We analytically obtain the topological phase diagram in the $(U/t)-\eta$ plane, which contains seven distinct phases. The topological properties of each phase are determined based on the bulk-edge correspondence. It is argued that the emergence of a fermionic many-body Majorana zero-energy edge state is a manifestation of the topological non-triviality of the system. We also discuss the duality relation between topological phases.

**Hamiltonian:** We consider a one-dimensional chain of spinless electrons: See Fig. The tight-binding model for a hybrid system comprised of the Kitaev model and the Su-Schrieffer-Heager (SSH) model together with the electron-electron interaction is given by

$$
H = -\mu \sum_j c_j^\dagger c_j - \sum_j t_j (c_j^\dagger c_{j+1} + \text{h.c.}) - \sum_j \Delta_j (c_j^\dagger c_{j+1} + \text{h.c.}) + \sum_j U_j \left(2c_j^\dagger c_j - 1\right) \left(2c_{j+1}^\dagger c_{j+1} - 1\right),
$$

with

$$
t_j = t \left\{ 1 - \eta (1-\eta)^2 \right\}, \quad \Delta_j = \Delta \left\{ 1 - \eta (1-\eta)^2 \right\},\nonumber$$

$$U_j = U \left\{ 1 - \eta (1-\eta)^2 \right\},
$$

where $\mu$ is the chemical potential, $t$ is the transfer integral, and $\Delta$ is the superconducting pairing gap taken to be real. Parameters $t_j, \Delta_j$ and $U_j$ are dependent of sites due to the dimerization $\eta$. We assume $t \geq 0$ without loss of generality, since the local unitary transformation $c_j \rightarrow -i (1-\eta)^2 c_j$ interchanges $t$ and $-t$. In addition, we assume $\Delta \geq 0$ since the phase transformation $c_j \rightarrow ic_j$ interchanges $\Delta$ and $-\Delta$. Without the interaction this Hamiltonian is reduced to the dimerized KTSC model.

**Jordan-Wigner transformation:** The model with no dimerization is exactly solvable for the case of $\Delta = t$ and $\mu = 0$.

We now show that, even if we include the dimerization $\eta$, it is exactly solvable for the case of $\Delta = t$ and $\mu = 0$. We consider the Jordan-Wigner transformation, representing the fermion operators in terms of the spin operator, such that $c_i = K_i \sigma_i^{-} \text{ and } c_i = \sigma_i^{\dagger} K_i^{\dagger}$, with $K_i = \prod_{j=-M}^{i-1} (-\sigma_j^z)$ and $\sigma_i^z = \sigma_i^+ \pm i\sigma_i^-$. It follows that

$$
\sigma_i^x \sigma_{i+1}^x = c_i^1 c_{i+1}^1 + c_i^1 c_{i+1}^1 c_i^1 c_{i+1}^1 + c_{i+1}^1 c_i^1,
$$

and

$$
\sigma_i^y \sigma_{i+1}^y = \left(2c_i^1 c_i^1 - 1\right) \left(2c_{i+1}^1 c_{i+1}^1 - 1\right).
$$

The Hamiltonian is rewritten in terms of the spin operator as

$$
H = \sum_j (-t_j \sigma_j^x \sigma_{j+1}^x + U_j \sigma_j^y \sigma_{j+1}^y),
$$

which is the XZ spin model with dimerization. It is customary to make a spin rotation by $\pi/2$ around the $x$ axis.
in the momentum space, with

\[
\mathcal{H}(k) = \begin{pmatrix}
0 & z & 0 & w \\
z^* & 0 & -w^* & 0 \\
0 & -w & 0 & -z \\
w^* & 0 & -z^* & 0
\end{pmatrix},
\]

where

\[
z(k) = -(t + U) \left[ (1 + \eta) + (1 - \eta) e^{-ika} \right],
\]

\[
w(k) = -(t - U) \left[ (1 + \eta) - (1 - \eta) e^{-ika} \right],
\]

and \( \alpha \) is the lattice constant. Diagonalizing this Hamiltonian we obtain the eigenvalues and the eigenfunctions explicitly.

In particular, the eigenvalues are

\[
E^2(k) / 4 = (1 \pm \eta)^2 t^2 + (1 \mp \eta)^2 U^2 - 2tU \left( 1 - \eta^2 \right) \cos k.
\]

The gap closes for

\[
\eta = \pm \left( t - U / (t + U) \right), \quad \pm \left( t + U / (t - U) \right).
\]

These gap-closing conditions generate the phase boundaries. There are seven distinct phases as in Fig. 2.3.

Our next task is to determine the topological properties of each phase. However, we cannot discuss the topological properties of the original system with the use of the Jordan-Wigner transformed operator \( f_j \) since it is given by a non-local transformation. Note that the topological properties are not conserved by such a transformation. Nevertheless, it is possible to discuss them by examining the edge state based on the bulk-edge correspondence by considering a semi-infinite chain with one edge.

**Majorana edge states:** First we show that there are two types of edge states. We introduce the Majorana representation \( \lambda^B_j = f_j + f_j^\dagger \) and \( \lambda^A_j = i(f_j - f_j^\dagger) \), and rewrite the Hamiltonian (10) in the Majorana form,

\[
H = i \sum_j t_j \lambda^B_{j+1} + U \lambda^A_j \lambda^B_j. \tag{17}
\]

This is separated into two independent Hamiltonians as \( H = H_1 + H_{11} \) with

\[
H_1 = \sum_j -iU \sum_j \phi^A_{j+1} \phi^B_j, \quad \phi^A_j = i(f_j - f_j^\dagger), \quad \phi^B_j = f_j + f_j^\dagger \tag{18}
\]

\[
H_{11} = \sum_j -iU \sum_j \phi^A_{j+1} \phi^B_j, \quad \phi^A_{j+1} \phi^B_j \tag{19}
\]

where we have defined \( \phi^A_j = \lambda^A_{j+1} \), \( \phi^B_j = \lambda^B_{j+1} \), \( \phi^A_{j+1} \phi^B_j \), \( \phi^A_{j+1} \phi^B_j \), and \( \phi^A_{j+1} \phi^B_j \). This decoupling is in essence of the relation between the XY model in zero field and two independent transverse-field Ising models.

The Jordan-Wigner transformed Majorana operators \( \lambda^\mu_j \) in the Bogoliubov-de Gennes form. We obtain

\[
\phi^A_{j+1} \phi^B_j = \gamma^A_j \prod_{k=1}^{j-1} (i \gamma^A_k \gamma^B_k + 1) \tag{20}
\]

\[
\phi^B_{j+1} \phi^A_j = \gamma^B_j \prod_{k=1}^{j-1} (i \gamma^B_k \gamma^A_k + 1) \tag{21}
\]

\[
\phi^A_{j+1} \phi^B_j = \gamma^A_j \prod_{k=1}^{j-1} (i \gamma^B_k \gamma^A_k + 1) \tag{22}
\]

\[
\phi^B_{j+1} \phi^A_j = \gamma^B_j \prod_{k=1}^{j-1} (i \gamma^A_k \gamma^B_k + 1) \tag{23}
\]
where we have defined $\gamma^A = c^I_j + c^I_j$ and $\gamma^B = i(c^I_j - c^I_j)$.

The zero-energy edge states of a semi-infinite chain are constructed by operating the linear combination of the operators $Q^\nu_I = \sum_{\nu,j} \alpha_{\nu,j} \phi^\nu_{\nu,j}$ to the Fock vacuum $|\text{vac}\rangle$, with $\mu = A, B$ and $\nu = I, \eta$, where the coefficients are given by\cite{24}

$$\alpha_{I,j} = -\left(\frac{U(1+\eta)}{t(1-\eta)}\right)^j, \quad \alpha_{II,j} = -\left(\frac{t(1+\eta)}{U(1-\eta)}\right)^j. \tag{24}$$

The edge is either the $A$ site or the $B$ site, according to which we use the many-body Majorana operator $Q^A_I$ or $Q^B_I$.

The condition for the convergence of the edge state is given by $|\alpha^{|\nu,j}| < 1$ for $\nu = I$ and $II$. This is actually the condition for the emergence of the zero-energy edge state in Hamiltonian $H_\nu$. For instance, if $|\alpha^{|\nu,j}| > 1$ there is no zero-energy edge state in the Hamiltonian $H_I$. Hence, for each phase of the phase diagram we calculate \cite{24} to decide whether $|\alpha^{|\nu,j}| < 1$ or not, and determine the number $Q_\nu$ of the type-$\nu$ edge states. We show the results in the phase diagram as in Fig.2(a).

**Topological properties:** The Hamiltonian \cite{4} does not conserve the fermion number $N = \sum_j c^I_j c^I_j$ due to the superconducting pairing term but conserves the fermion parity defined by $Z^I_2 = (-1)^N$ since the superconducting pairing term only changes the fermion number by two. It commutes (anticommutes) with any product of an even (odd) number of fermion operators. It is rewritten in terms of the Majorana operator as $Z^I_2 = \prod_j i\gamma_j^A \gamma_j^B$. We find that $\{Q^I_{\nu}, Z^I_2\} = 0$ and $[Q^I_{II}, Z^I_2] = 0$. Hence, the type-I edge states are fermionic, while the type-II edge states are bosonic.

According to the bulk-edge correspondence, zero-energy edge states necessarily emerge if the system is topological but the reverse is not true. On one hand, it follows from \cite{24} that the type-I edge state is adiabatically connected to a non-interacting Majorana zero-energy state as $U \rightarrow 0$, where it is shown to be topological based on the well-defined topological argument. On the other hand, since the type-II edge state disappears except for the $\eta = -1$ case, it is connected to a trivial state as $U \rightarrow 0$. It is bosonic, as we have mentioned. Consequently, the system with the type-I edge state is topological, while that with the type-II edge state is trivial \cite{24}.

**TSC, CDW and CAT phases:** We have found seven distinct phases. We investigate their topological and ground-state properties more in details. First, we focus on the three phases along the $\eta = 0$ line in Fig.2(a). They are already known \cite{24} and named the topological-superconductor (TSC), charge-density-wave (CDW) and Schrödinger-cat (CAT) phases. The Schrödinger-cat state is a superposition of two superconducting states with different occupation numbers \cite{24}. These ground-state properties are extended into the two-dimensional regions as in Fig.2(a) for $\eta \neq 0$, and hence we use the same names also for the two-dimensional phases. We note that the points $(U/t, \eta) = (\pm 1, 0)$ are tetra-critical points at which four distinct phases touch. It has been shown \cite{24,4} that the TSC phase is topological while the CDW and CAT phases are trivial, which are consistent with the present results.

**Dimer state:** There are four phases which are absent for $\eta = 0$. We name them as the single-electron-dimer (SED) phases, and the superconducting-dimer (SCD) phases by the ground-state properties. Their ground-state properties and topological properties are made manifest in the strong dimerization limit $\eta = \pm 1$.

For $\eta = 1$ the system is separated into independent dimers as in Fig.1(a). The Hamiltonian \cite{4} reads $H = \sum_j \epsilon_{2j-1,2j}$,
where for instance we have

\[ H_{1,2} = -t \left[ c_1^\dagger c_2 + c_2^\dagger c_1 \right] - \Delta \left[ c_1^\dagger c_2^\dagger + c_2 c_1 \right] + U \left( 2c_1^\dagger c_1 - 1 \right) \left( 2c_2^\dagger c_2 - 1 \right). \]  

(25)

The diagonalization is straightforward (23). We note that, since the two-site Hamiltonian commutes with the fermion parity operator \( Z_2 \), the Hilbert space is decomposed into two subspaces containing even or odd numbers of electrons.

The even subspace is composed of the following two states,

\[ |00\rangle \equiv |\text{vac}\rangle \quad \text{and} \quad |11\rangle \equiv c_1^\dagger c_2^\dagger |\text{vac}\rangle, \]

(26)

corresponding to there are no electrons or two electrons. The Hamiltonian in the basis of \( \{|00\rangle, |11\rangle\} \) is given by

\[ H = \begin{pmatrix} U & -\Delta \\ -\Delta & -U \end{pmatrix}, \]

(27)

which yields the energy dispersion \( E_{\pm}^{\text{even}} = U \mp \Delta \) with the eigenfunction \( \psi_{\pm}^{\text{even}} = \frac{1}{\sqrt{2}}(|00\rangle \pm |11\rangle) \).

The odd subspace is composed of the following two states,

\[ |10\rangle \equiv c_1^\dagger |\text{vac}\rangle \quad \text{and} \quad |01\rangle \equiv c_2^\dagger |\text{vac}\rangle, \]

(28)

corresponding to one electron states occupying the first site or the second site. The Hamiltonian in the basis of \( \{|10\rangle, |01\rangle\} \) is given by

\[ H = \begin{pmatrix} -U & -t \\ -t & -U \end{pmatrix}, \]

(29)

which yields the energy dispersion \( E_{\pm}^{\text{odd}} = -U \mp t \) with the eigenfunction \( \psi_{\pm}^{\text{odd}} = \frac{1}{\sqrt{2}}(|10\rangle \pm |01\rangle) \).

We may derive the following results. On one hand, when the interaction is repulsive \( (U > 0) \), the ground state is a symmetric single electron hopping state \( \psi_{\pm}^{\text{even}} = \frac{1}{\sqrt{2}}(|00\rangle \pm |11\rangle) \) with the energy \( E_{\pm}^{\text{odd}} = -U - t \). It is reasonable to call it the SED state. On the other hand, when the interaction is attractive \( (U < 0) \), it is a symmetric superconducting state \( \psi_{\pm}^{\text{even}} = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle) \) with the energy \( E_{\pm}^{\text{even}} = U - \Delta \). Since the state contains a pair of electrons, it is reasonable to call it the SCD state. Since there exist no zero-energy states, the system is topologically trivial.

For \( \eta = -1 \) the semi-infinite chain system is separated into independent dimers and an extra single site at the edge, as in Fig.1(e). The analysis of the dimer parts is precisely the same as in the limit \( \eta = 1 \). The single electron at the edge plays a key role, since its energy is zero in the absence of the chemical potential \( (\mu = 0) \). There exist two zero-energy states; the state \( |0\rangle = |\text{vac}\rangle \) is bosonic, while the state \( |1\rangle = c_1^\dagger |\text{vac}\rangle \) is fermionic. The emergence of the fermionic zero-energy state is a manifestation of the topological nontriviality of the system.

These basic properties remain almost as they are for \( \eta \neq \pm 1 \). At least in the region near \( \eta = \pm 1 \), the ground state is a linear superposition of individual dimers [Fig.1(b) and (d)]. There are trivial dimer phases for \( \eta > 0 \), while there are topological dimer phases for \( \eta < 0 \), which is differentiated by the emergence of the zero-energy edge state, as shown in Fig.1(c)–(e). We find there is no zero-energy state for \( \eta > 0 \), while there are two zero-energy states per one edge for \( \eta < 0 \), which are the type-I and the type-II edge states. In the topological phase, there is an unpaired site at the edge of a semi-infinite chain [Fig.1(d) and (e)], which results in the zero-energy edge states. We note that the topological and trivial phases alter once we take a half-shifted unit cell, which is a reminiscence of the SSH model (28).

**Duality:** The system has several duality relations (19). The system (10) with \( \eta = 0 \) is self-dual (23) for \( U = t \). We generalize it to the case that \( \eta \neq 0 \). The Hamiltonian (17) is invariant under the duality transformation, \( t \leftrightarrow U \) and \( \lambda_j^A \leftrightarrow \lambda_j^B \). For \( \eta = 0 \), there is only one transition point for \( U/t > 0 \), while the self-duality determines the transition point as \( U = t \). For \( \eta \neq 0 \), there are two transition points at \( \eta = \pm (t - U) / (t + U) \) corresponding to (16), which are exchanged by the duality transformation.

The Hamiltonian is invariant also under the duality transformation, \( t \leftrightarrow -U \) and \( \lambda_j^A \leftrightarrow (-1)^j \lambda_j^B \), for which a similar argument follows. For \( \eta = 0 \), there is only one transition point for \( U/t < 0 \), where the self-duality determines the transition point as \( U = -t \). For \( \eta \neq 0 \), there are two transition points at \( \eta = \pm (t + U) / (t - U) \) corresponding to (16), which are exchanged by the duality transformation.

Finally, the Hamiltonian is invariant also under the duality transformation, \( U \leftrightarrow -U \) and \( \lambda_j^B \leftrightarrow (-1)^j \lambda_j^B \). For \( \eta \neq \pm 1 \), there are two transition points, \( U/t = (1 \pm \eta) / (1 \mp \eta) \) and \( - (1 \mp \eta) / (1 \pm \eta) \) corresponding to (16), which are exchanged by the duality transformation (the upper signs for \( \mu > 0 \) and the lower signs for \( \mu < 0 \)). For \( \eta = \pm 1 \), there is only one transition point \( U/t = 0 \), where the system is self-dual.

The author is very much grateful to N. Nagaosa, J.H.H. Perk, H. Katsura and J. Knolle for helpful discussions on the subject. This work is supported by the Grants-in-Aid for Scientific Research from MEXT KAKENHI (Grant Nos. JP17K05490 and JP15H05854). This work is also supported by CREST, JST (JPMJCR16F1).

**Note added:** After submission of the manuscript, a closely related paper (27) was uploaded in cond-mat/arXiv, where an exact solution on a similar interacting dimerized topological superconductor is obtained by using the same method. There is a difference between the two models that the interaction \( U \) is not dimerized in the above paper. Their results are consistent with ours.
