Received September 10, 1998 / Accepted November 5, 1998

Abstract. Strömgren synthetic photometry from an empirically calibrated grid of stellar atmosphere models has been used to derive the effective temperature of each component of double lined spectroscopic (SB2) eclipsing binaries. For this purpose, we have selected a sub-sample of 20 SB2s for which (b−y), m\(_1\), and c\(_1\) individual indices are available. This new determination of effective temperature has been performed in a homogeneous way for all these stars. As the effective temperature determination is related to the assumed metallicity, we explore simultaneous solutions in the (T\(_{\text{eff}},[\text{Fe/H}]\))-plane and present our results as confidence regions computed to match the observed values of surface gravity, (b−y), m\(_1\), and c\(_1\), taking into account interstellar reddening. These confidence regions show that previous estimates of T\(_{\text{eff}}\) are often too optimistic, and that [Fe/H] should not be neglected in such determinations. Comparisons with Ribas et al. (1998) using Hipparcos parallaxes are also presented for 8 binaries of our working sample, showing good agreement with the most reliable parallaxes. This point gives a significant weight to the validity of the BaSeL models for synthetic photometry applications.

Key words: Stars: fundamental parameters – Stars: binaries – Stars: statistics

1. Introduction

Fundamental stellar parameters such as masses and radii of well detached double-lined spectroscopic eclipsing binaries can be determined very accurately (Andersen 1991). Therefore, from accurate (1-2\%) stellar mass and radius determinations of such objects, one can compute surface gravities to very high and otherwise inaccessible confidence levels. Indeed, Henry & Mc Carthy (1993) have discussed the data available for visual binaries of solar mass and below. Only α Cen B (G2V,0.90 M⊙) has a mass known with an accuracy comparable to that for favorable eclipsing binaries. This point shows the importance of choosing such double-lined eclipsing binaries in order to obtain surface gravities with the highest possible accuracy. Moreover, these binaries are of great interest to perform accurate tests of stellar evolutionary models (see e.g. Lastennet et al. 1996, Pols et al. 1997, Lastennet & Valls-Gabaud 1998) used to derive cluster ages. The knowledge of all possible stellar parameters for such single stars is the basis of the modelling of the global physical properties and evolution of star clusters or galaxies. Nevertheless, while masses and radii are accurately known, the effective temperatures – and consequently, the luminosities of these stars – strongly depend upon the calibration used to relate photometric indices with T\(_{\text{eff}}\). As a matter of fact, for such binaries the temperatures given in the literature come from various calibration procedures and are indeed highly inhomogeneous. Furthermore, due to the lack of empirical calibrations at different metallicities, solar metallicity is often assumed for photometric estimations of T\(_{\text{eff}}\). In this regard, synthetic photometry performed from large grids of stellar atmosphere models, calibrated in T\(_{\text{eff}}\), log g, and [Fe/H], provides a powerful tool of investigation. In this paper, we explore simultaneous solutions of T\(_{\text{eff}}\) and [Fe/H], and we address the question of the reliability of metallicity-independent effective temperature determinations.

We have selected 20 binary systems (40 stars) for which we have uvby Strömgren photometry with estimated errors (see Table 1). For this sample, previous estimates of effective temperature are not homogeneous, originating from various calibrations established for different spectral-type domains: Morton & Adams (1968), Relyea & Kurucz (1978), Osmer & Peterson (1974), Grosbol (1978), Davis & Shobbrook (1977), Popper (1980), Moon & Dworetsky (1985), Saxner & Hammarbäck (1985), Jakobsen (1986), Magain (1987), Napiwotzki et al. (1993), and Edvardsson et al. (1993). Moreover, all these studies are of course historically not fully independent. As an example, the T\(_{\text{eff}}\)
of Moon & Dworetsky (1985) is estimated using the $T_{\text{eff}}$, $(B-V)_0$ calibration of Hayes (1978) and the $T_{\text{eff}}$, $c_0$ calibration of Davis & Shobbrook (1977). However, this does not mean that these calibrations allow to derive very similar temperatures. As highlighted by Andersen & Clausen (1989) concerning the O-type components of EM Carinae, the temperature calibration of Davis & Shobbrook (1977), Jakobsen (1986), and Popper (1980) do not agree particularly well. A similar comparison of these three calibrations made by Clausen & Giménez (1991) with the massive B-type components of CW Cephei leads to $\Delta T_{\text{eff}} \sim 5500K$!

Thus, a new and homogeneus determination of effective temperature is of primordial interest for such well-known objects. In order to re-derive in a homogeneous way the $T_{\text{eff}}$ of these stars, we have used the Basel Stellar Library (hereafter “BaSeL”) which provides empirically calibrated model spectra over a large range of stellar parameters (Lejeune et al. 1997, 1998a).

In Section 2 we will describe the models used to perform our calculation of $T_{\text{eff}}$ from uvby Strömgren photometry. Sect. 3 will be devoted to the description of the method and the presentation of the results.

2. Model colours

The BaSeL models cover a large range of fundamental parameters: $2000 \text{ K} \leq T_{\text{eff}} \leq 50,000 \text{ K}$, $-1.02 \leq \log g \leq 5.5$, and $-5.0 \leq [\text{M/H}] \leq +1.0$. This library combines theoretical stellar energy distributions which are based on several original grids of blanketed model atmospheres, and which have been corrected in such a way as to provide synthetic colours consistent with extant empirical calibrations at all wavelengths from the near-UV through the far-IR (see Lejeune et al. 1997, 1998a). For our purpose, we have used the new version of the BaSeL models for which the correction procedure of the theoretical spectra has been extended to higher temperatures ($T_{\text{eff}} \geq 12,000 \text{ K}$), using the $T_{\text{eff}}$–$(B-V)$ calibration of Flower (1996), and to shorter wavelengths (Lejeune et al. 1998b).

Because the correction procedure implies modulations of the (pseudo-)continuum which are smooth between the calibration wavelengths, the final grid provides colour-calibrated flux distributions ($9.1 \leq \lambda \leq 160,000$ nm, with a mean resolution of $1 \sim 2$ nm from the UV to the visible) which are also suitable for calculating medium-band synthetic photometry, such as Strömgren colours. Thus, synthetic Strömgren photometry was performed using the passband response functions $(u, v, b, y)$ given in Schmidt-Kaler (1982). Theoretical $(u-b)$, $(b-y)$, $m_1 = (v-b) - (b-y)$, and $c_1 = (u-v) - (v-b)$ indices have been computed, where the zero-points were defined by matching the observed colours $(u-b = 1.411, b-y = 0.004, m_1 = 0.157, c_1 = 1.089$; Hauck & Mermilliod 1980) of Vega with those predicted by the corresponding Kurucz (1991) model for $T_{\text{eff}} = 9400 \text{ K}$, $\log g = 3.90$, $[\text{M/H}] = -0.50$.

3. Effective temperature determination

3.1. Strömgren data

Among the approximately sixty SB2 systems gathered in Lastennet (1998), only 20 have both individual uvby Strömgren photometric indices and uncertainties for each component. Uncertainties are a key point in the calculation presented later (Sect. 3.2). The photometry used for the 20 systems of our working sample (see Table 1) is from the recent Table 5 of Jordi et al. (1997), who have taken the individual indices directly from the literature but have also added their own results for three systems (YZ Cas, WX Cep, and IQ Per).

3.2. Methodology

To compute synthetic colours from the BaSeL models, we need effective temperature ($T_{\text{eff}}$), surface gravity ($\log g$), and metallicity ($[\text{Fe/H}]$). Consequently, given the observed colours (namely, $b-y, m_1$, and $c_1$), we are able to derive $T_{\text{eff}}, \log g$, and $[\text{Fe/H}]$ from a comparison with model colours. As the surface gravities can be derived very accurately from the masses and radii of the stars in our working sample, only two physical parameters have to be derived ($T_{\text{eff}}$ and $[\text{Fe/H}]$).

This has been done by minimizing the $\chi^2$-functional, defined as

$$\chi^2(T_{\text{eff}}, [\text{Fe/H}]) = \sum_{i=1}^{n} \left( \frac{\text{colour}(i)_{\text{syn}} - \text{colour}(i)}{\sigma(\text{colour}(i))} \right)^2,$$

where $n$ is the number of comparison data, colour(1) = $(b-y)_0$, colour(2) = $m_0$, and colour(3) = $c_0$. The best $\chi^2$ is obtained when the synthetic colour, colour(1)_{syn}, is equal to the observed one.

Reddening has been taken into account following Crawford (1975): $(b-y)_0 = (b-y) - E(b-y)$, $m_0 = m_1 + 0.3 \times E(b-y)$, $c_0 = c_1 - 0.2 \times E(b-y)$, in order to derive the intrinsic colours from the observed ones. With $n = 3$ observational data ($b-y, m_1, c_1$) and $p = 2$ free parameters ($T_{\text{eff}}$ and $[\text{Fe/H}]$), we expect to find a $\chi^2$-distribution with $q = n - p = 1$ degree of freedom. Finding the central minimum value $\chi_{\text{min}}^2$, we form the $\chi^2$-grid in the ($T_{\text{eff}}$ and $[\text{Fe/H}]$)-plane and compute the boundaries corresponding to $1\sigma$, $2\sigma$, and $3\sigma$ respectively. As our sample contains only stars belonging to the Galactic disk, we have explored a restricted range of metallicity, $-1.0 \leq [\text{Fe/H}] \leq +0.5$.

Figure 4 illustrates the different steps of the method, here for BW Aqr A. All possible combinations of observational data (as indicated on the top of each panel) are explored, hence varying the number of degrees of freedom for minimizing the $\chi^2$. The top panels show the results obtained for matching uniquely one colour index ($b-y, m_1$, or $c_1$). In these cases, $q = n - p = -1$, which simply means that it is impossible to fix both $T_{\text{eff}}$ and $[\text{Fe/H}]$ with
only one observational quantity, as indeed is illustrated by the three top panels of Fig. 1. From (b−y) only, the effective temperature boundaries appear to be very similar across the whole metallicity range, highlighting the fact that this index is traditionally used to derive $T_{\text{eff}}$. Alternatively, the $m_1$ index only provides constraints on the metallicity of the star. Used together (lower central panel), these two indices outline restricted “islands” of solutions in the ($T_{\text{eff}}$, [Fe/H])-plane, and hence offer a good combination to estimate these parameters. The $c_1$ index has been originally designed to estimate the surface gravity, but it also appears to be a good indicator of temperature in the parameter range explored for BW Aqr A (upper right panel). On the lower right panel, all the available observational information (b−y, $m_1$, $c_1$, and log $g$) can be exploited. The range of $T_{\text{eff}}$ values that we then derive for BW Aqr A agree well with previous estimates (as indicated by the vertical dotted lines), and the same is true for its metallicity, which is compatible with the Galactic disk stars. Finally, in order to take full advantage of all the observational information available for the stars in our sample, we choose to estimate $T_{\text{eff}}$ and [Fe/H] from a $\chi^2$ minimization performed on the three colour indices.

3.3. Surface gravity accuracy and influence of reddening

3.3.1. Surface gravity

As our results depend not only on the accuracy of the photometric data, but also on that of the surface gravity determination, we analysed the effect of a variation of log $g$ upon the predicted $T_{\text{eff}}$ and [Fe/H] values. We investigated this “log $g$ effect” for the AR Aur system, for which the known value of log $g$ has the largest uncertainties in our working sample: for instance, the surface gravity of the coolest component of AR Aur (AR Aur B) is log $g = 4.280 \pm 0.025$.

For log $g = 4.280$, the central $T_{\text{eff}}$ value predicted is about 10,500K. If we consider log $g = 0.025$ dex (left panel in Fig. 2) or log $g = 0.025$ dex (right panel in Fig. 2), neither the central $T_{\text{eff}}$ value nor the pattern of contours change significantly.

This example shows that our results for ($T_{\text{eff}}$, [Fe/H]) will not change due to variations of surface gravity within the errors listed in Table 1.

3.3.2. Interstellar reddening

Interstellar reddening is of prime importance for the determination of both $T_{\text{eff}}$ and [Fe/H]. A great deal of attention was therefore devoted to the $E(b−y)$ values available in the literature, for each star of our sample. We explore different reddening values (as described in Sect. 3.2), and we compare their resulting $\chi^2$-scores. For the following systems, we adopted the published values, in perfect agreement with our results: BW Aqr, AR Aur, β Aur, GZ Cnc, EM Car, CW Cep, GG Lup, TZ Men, V451 Oph, AI Phe, ζ Phe, VV Pyx, and DM Vir. As we did not find any indication about the interstellar reddening of YZ Cas, we kept $E(b−y) = 0$ as a quite reasonable hypothesis. We have neither found any data on interstellar reddening for the WX Cephei system. But the hypothesis of no significant reddening for WX Cep is ruled out by the very

Fig. 1. Simultaneous solutions of $T_{\text{eff}}$ and [Fe/H] for BW Aqr A (assuming log $g = 3.981$): matching (b−y) (upper left), $m_1$ (upper central), $c_1$ (upper right), (b−y), and $c_1$ (lower left), (b−y), and $m_1$ (lower central), (b−y), $m_1$, and $c_1$ (lower right). Best fit (black dot) and 1-σ (solid line), 2-σ (dashed line), and 3-σ (dot-dashed line) confidence levels are also shown. Previous estimates of $T_{\text{eff}}$ from Clausen (1991) are indicated as vertical dotted lines in all panels.

Fig. 2. Influence of log $g$ on the simultaneous solution of $T_{\text{eff}}$ and [Fe/H] for AR Aur B. Two different log $g$ values are considered: log $g = 4.255$ (left panel), log $g = 4.305$ (right panel). These values are 0.025 dex higher or lower than the true log $g$ (4.280).

For log $g = 4.280$, the central $T_{\text{eff}}$ value predicted is about 10,500K. If we consider log $g = 0.025$ dex (left panel in Fig. 2) or log $g = 0.025$ dex (right panel in Fig. 2), neither the central $T_{\text{eff}}$ value nor the pattern of contours change significantly.
high $\chi^2$-value obtained in reproducing simultaneously the quadruplet (b−y, m$_1$, c$_1$, log g) of the observed data. From the different reddening values explored in Table 2, we find that E(b−y) = 0.32 for WX Cep A and E(b−y) = 0.28 for WX Cep B provide the best solutions.

Table 2. Influence of reddening on the $\chi^2$ of the components of the WX Cephei system. Best $\chi^2$ are in bold characters. The hypothesis of no reddening is definitively ruled out.

| E(b−y) | WX Cep A $\chi^2$-values | WX Cep B $\chi^2$-values |
|--------|--------------------------|---------------------------|
| 0.00   | 912.890                  | 115.290                   |
| 0.26   | 29.039                   | 0.933                     |
| 0.28   | 10.974                   | **0.682**                 |
| 0.30   | 4.549                    | 1.210                     |
| 0.32   | **4.009**                | 2.651                     |
| 0.34   | 4.322                    | 4.972                     |

The influence of reddening variations is illustrated in Figure 3. While for the system, WX Cep AB, an average value E(b−y) = 0.30 appears justified from the results of Table 2 and will indeed be adopted in the remainder of this paper. Figure 3 shows how for the individual component, WX Cep A, small changes $\Delta E$(b−y) = ±0.02 away from its own optimum value E(b−y) = 0.32 induce significant changes in the possible solutions of the ($T_{\text{eff}}$, [Fe/H])-couples. In particular, going to E(b−y) = 0.30 (upper right panel) implies a dramatic jump in predicted [Fe/H] from a (plausible) metal-normal (lower left) to a (rather unlikely ?) metal-poor composition at or near the lower limit ([Fe/H] = −1) of the exploration range.

For the other four systems for which interstellar reddening has also been previously neglected in the literature, we found small, but not significant, E(b−y) values: RZ Cha (0.003), KW Hya (0.01), V1031 Ori (0.05), and PV Pup (0.06).

E(b−y) = 0.11 has been adopted for IQ Per by comparing different $\chi^2_{\text{min}}$ solutions. This value is consistent with E(b−y) = 0.10±0.01, estimated from the published value of E(B−V) = 0.14±0.01 (Lacy & Frueh 1985), assuming E(b−y) = 0.73 × E(B−V) after Crawford (1975). Adopted reddening values for stars of our sample are listed in Table 1.  

3.4. General results and discussion

In Figures 4 and 5 we show the full results obtained (from b−y, m$_1$, and c$_1$) for all the stars of the sample in ($T_{\text{eff}}$, [Fe/H]) planes. All the ($T_{\text{eff}}$, [Fe/H])-solutions inside the contours allow to reproduce, at different confidence levels, both the observed Strömgren colours (b−y, m$_1$, and c$_1$) and the surface gravity with the BaSeL models. As a general trend, it is important to notice that our $T_{\text{eff}}$ ranges do not provide estimates systematically different from previous ones (vertical dotted lines). Furthermore, the 3-$\sigma$ confidence regions show that most previous $T_{\text{eff}}$ estimates are optimistic, except for some stars (e.g., GG Lup A, TZ Men A, and V451 Oph A) for which our method gives better constraints on the estimated effective temperature. At a 1-$\alpha$ confidence level (68.3%), our method often provides better constraints for $T_{\text{eff}}$ determination. However, it is worth noticing that for a few stars the match is really bad (see $\chi^2_{\text{min}}$-values labelled directly on Fig. 4 and 5). As already mentioned, with 3 observational data (b−y, m$_1$, c$_1$) and 2 free parameters ($T_{\text{eff}}$ and [Fe/H]), we expect to find a $\chi^2$-distribution with 3−2=1 degree of freedom and a typical $\chi^2_{\text{min}}$-value of about 1. For some stars (e.g. VV Pyx, DMVir and KW Hya A), $\chi^2_{\text{min}}$ is greater than 10, a too high value to be acceptable because the probability to obtain an observed minimum $\chi$-square greater than the value $\chi^2=10$ is less than 0.2%. For this reason, the results given for a particular star should not be used without carefully considering the $\chi^2_{\text{min}}$-value.

One of the most striking features appearing in nearly all panels of Figs. 4 and 5 is the considerable range of [Fe/H] accepted inside the confidence levels. This is particularly true for stars hotter than $\sim$10,000 K (as, for instance, EM Car A & B and GG Lup A & B), for which optical photometry is quite insensitive to the stellar metal content. For these stars, a large range in [Fe/H] gives very
similar $\chi^2$ values. In contrast, for the coolest stars in our sample, our method provides straight constraints on their metallicity. Actually, when observational metallicity indications are available ($\beta$ Aur, YZ Cas, RZ Cha, AI Phe, and PV Pup), the contour solutions are found in good agreement with previous estimated $[\text{Fe/H}]$ ranges (labelled as horizontal lines in Figs. 4 and 5).

The effective temperatures derived from our minimization procedure cannot be easily presented in a simple table format, as they are intrinsically related to metallicity. We nonetheless provide in Table 3, as an indication of the estimated stellar parameters for all the stars in our sample, the best ($\chi^2_{\text{min}}$) simultaneous solutions ($T_{\text{eff}}, [\text{Fe/H}]$) for the three following cases: by using $b-y$ and $m_1$ (Case 1), $b-y$ and $c_1$ (Case 2) and by using $b-y$, $m_1$, and $c_1$ (Case 3). In Case 1 and Case 2, a typical $\chi^2_{\text{min}}$-value close to zero is theoretically expected, and in Case 3, as previously mentioned, one expects a typical $\chi^2_{\text{min}}$-value of about 1. There are quite a few stars for which $\chi^2_{\text{min}}$ increases dramatically between Case 1 or 2 and Case 3 to a clearly unacceptable value (most notably AI Phe A between Case 1 and Case 3). This point means that although a good fit is obtained with two photometric indices, no acceptable $\chi^2_{\text{min}}$-value is obtained by adding one more index in Case 3. Consequently, Case 1 or Case 2-solutions have to be chosen in such cases. For these stars, even if the $\chi^2_{\text{min}}$ solutions shown in Figs. 4 and 5 are not reliable, it is interesting to notice that the contours derived are however still in agreement with previous works.

The surprising result in Table 3 is that many solutions are very metal-poor. This in fact means that the $\chi^2_{\text{min}}$ solutions are not necessarily the most realistic ones. We must, therefore, emphasize that the values presented in Table 3 should not be used without carefully considering the confidence level contours shown in Figs. 4 and 5. For most stars in our sample, $T_{\text{eff}}$ and $[\text{Fe/H}]$ do not appear strongly correlated (i.e. the confidence regions do not exhibit oblique shapes), but there are a few cases for which the assumed metallicity leads to a different range in the derived effective temperature (EM Car B, CW Cep A & B, GG Lup A, $\zeta$ Phe A). These results point out that the classical derivation of $T_{\text{eff}}$ from calibration without exploring all $[\text{Fe/H}]$ values is not always a reliable method, even for hot stars.

3.5. Comparison with Hipparcos parallax

Very recently, Ribas et al. (1998) have computed the effective temperatures of 19 eclipsing binaries included in the Hipparcos catalogue from their radii, Hipparcos trigonometric parallaxes, and apparent visual magnitudes corrected for absorption. They used Flower’s (1996) calibration to derive bolometric corrections. Only 8 systems are in common with our working sample. The comparison with our results is made in Table 4. The $T_{\text{eff}}$ being highly related with metallicity, a direct comparison is not possible because, unlike the Hipparcos-derived data, our results are not given in terms of temperatures with error bars, but as ranges of $T_{\text{eff}}$ compatible with a given $[\text{Fe/H}]$. Thus, the ranges reported in Tab. 4 are given assuming three different hypotheses: $[\text{Fe/H}]=-0.2$, $[\text{Fe/H}]=0$, and $[\text{Fe/H}]=0.2$. The overall agreement is quite satisfactory, as illustrated in Fig. 6.

The disagreement for the temperatures of CW Cephei can be explained by the large error of the Hipparcos parallax ($\sigma_{\pi}/\pi \approx 70\%$). For such large errors, the Lutz-Kelker correction (Lutz & Kelker 1973) cannot be neglected: the average distance is certainly underestimated and, as a consequence, the $T_{\text{eff}}$ is also underestimated in Ribas et al.’s (1998) calculation. Thus, the agreement with the results obtained from the BaSeL models is certainly better than it would appear in Fig. 6 and Tab. 4. Similar corrections, of slightly lesser extent, are probably also indicated for the $T_{\text{eff}}$ of RZ Cha and GG Lup, which have $\sigma_{\pi}/\pi > 10\%$ (11.6% and 11.4%, respectively). Finally, it is worth noting that the system with the smallest relative error in Tab. 4, $\beta$ Aur, shows excellent agreement between $T_{\text{eff}}$ (Hipparcos) and $T_{\text{eff}}$ (BaSeL), which underlines the validity of the BaSeL models.

4. Conclusion

The comprehensive knowledge of fundamental parameters of single stars is the basis of the modelling of star clusters and galaxies. Most fundamental stellar parameters of the individual components in SB2 eclipsing binaries are known with very high accuracy. Unfortunately, while masses and radii are well determined, the temperatures strongly depend on photometric calibrations. In this paper, we have used an empirically-calibrated grid of theoretical stellar spectra (BaSeL models) for simultaneously deriving homogeneous effective temperatures and metallicities from observed data. Although a few stars show an incompatibility between the observed and synthetic uvby colours if we try to match the three Strömgren indices ($b-y$), $m_1$, and $c_1$, the overall determinations are satisfying. Moreover, an acceptable solution is always possible when only considering two photometric indices, as in Case 1 or Case 2 (see Table 3). The large range of $[\text{Fe/H}]$ associated with acceptable confidence levels makes it evident that the classical method to derive $T_{\text{eff}}$ from metallicity-independent calibrations should be considered with caution. We found that, even for hot stars for which we expect optical photometry to be nearly insensitive to the stellar metal-content, a change in the assumed metallicity can lead to a significant change in the predicted effective temperature range. Furthermore, for cool stars, both $T_{\text{eff}}$ and $[\text{Fe/H}]$ can be estimated with good accuracy from the photometric method. The effects of surface gravity and interstellar reddening have also been carefully studied. In particular, an apparently minor error in reddening can change dramatically the shape of the confidence contour.
levels, and, therefore, the parameter values hence derived. By exploring the best $\chi^2$-fits to the photometric data, we have re-derived new reddening values for some stars (see Table 1). Finally, comparisons for 16 stars with Hipparcos-based $T_{\text{eff}}$ determinations show good agreement with the temperatures derived from the BaSeL models. The agreement is even excellent for the star having the most reliable Hipparcos data in the sample studied in this paper. These comparisons also demonstrate that, while originally calibrated in order to reproduce the broad-band (UBVRI-JHKL) colours, the BaSeL models also provide reliable results for medium-band photometry such as the Strömgren photometry. This point gives a significant weight to the validity of the BaSeL library for synthetic photometry applications in general.

1 this work (cf. Sect 3.3.2)
(a) Clausen (1991); (b) Popper et al. (1985); (c) Andersen & Clausen (1989); (d) Clausen & Giménez (1991); (e) Our value is consistent with E(b−y)=0.090±0.008 for A-stars (Crawford, 1979); (f) Andersen et al. (1993) using the (b−y)0–c0 relation of Crawford (1978); (g) Clausen et al. (1986) determined the reddening from the [u−b]–(b−y)0 relation for early-type stars of Strömgren & Olsen (unpublished) and the c0–(b−y)0 relation of Crawford (1973), which give nearly identical results; (h) Andersen et al. (1990) used E(b−y)= 0.0 but quote E(b−y)=0.025 as a possible value; (i) E(B−V)=0.14±0.01 (Lacy & Frueh 1985); (j) E(B−V)=0.02±0.02 (Hrivnak & Milone 1984); (k) Andersen et al. (1984) using the calibrations of Grobsol (1978); (l) Moon & Dworetsky (1985); (m) At the best of our knowledge, systems for which interstellar reddening has been neglected or considered as insignificant in the literature.

Note: we assume E(b−y)=0.73×E(B−V) after Crawford (1975).
Fig. 4. Simultaneous solution of $T_{\text{eff}}$ and $[\text{Fe/H}]$ matching ($b-y)_0$, $m_0$, $c_0$, and $\log g$. The name of the star and the $\chi^2_{\text{min}}$ are labelled directly in each panel. When available, effective temperature determinations from previous studies (vertical lines) and observational indications of metallicity (horizontal lines) are also shown.
Fig. 5. Same as Fig. 4.
Table 3. Best simultaneous \((T_{\text{eff}}, [\text{Fe/H}])\) solutions using \((b-y)\) and \(m_1\) (Case 1), \((b-y)\) and \(c_1\) (Case 2) or \((b-y), m_1\), and \(c_1\) (Case 3).

| Name     | Case 1 |          | Case 2 |          | Case 3 |          |
|----------|--------|----------|--------|----------|--------|----------|

Fig. 6. Hipparcos- versus BaSeL-derived effective temperatures for β Aur, YZ Cas, CW Cep, RZ Cha, KW Hya, GG Lup, TZ Men, and ζ Phe. The errors are not shown on the Hipparcos axis for CW Cephei (the hottest binary in these figures). See text for explanation.
