Molecular Detection of Bartonella quintana, B. koehlerae, B. henselae, B. clarridgeiae, Rickettsia felis, and Wolbachia pipiens in Cat Fleas, France

Jean-Marc Rolain,* Michel Franc,† Bernard Davoust,‡ and Didier Raoult*

The prevalences of Bartonella, Rickettsia, and Wolbachia were investigated in 309 cat fleas from France by polymerase chain reaction (PCR) assay and sequencing with primers derived from the gltA gene for Rickettsia, the its and pap31 genes for Bartonella, and the 16S rRNA gene for Anaplasmataceae. Positive PCR results were confirmed by using the Lightcycler and specific primers for the rOmpB of Rickettsia and gltA of Bartonella. R. felis was detected in 25 fleas (8.1%), W. pipiensis, an insect symbiont, in 55 (17.8%), and Bartonella in 81 (26.2%), including B. henselae (9/81; 11.1%), B. clarridgeiae (55/81; 67.9%), B. quintana (14/81; 17.3%), and B. koehlerae (3/81; 3.7%). This is the first report of the amplification of B. quintana from fleas and the first description of B. koehlerae in fleas from an area outside the United States. Cat fleas may be more important vectors of human diseases than previously reported.

Fleas can be found worldwide and are vectors of several important zoonoses, including plague caused by Yersinia pestis (1). The classic cycle of Rickettsia typhi, the agent of murine typhus, involves rats and the rat flea, Xenopsylla cheopis, the main vector (2). The disease is transmitted by flea bites or contact with flea feces. Recently, murine typhus has been shown to exist in some endemic foci where neither rats nor their fleas are found. Subsequently, in the United States, R. typhi was found to be maintained in the cat flea, Ctenocephalides felis, collected from opossums (2). R. felis is the recently recognized agent of flea-borne spotted fever, which has been reported in various countries, including the United States, Mexico, Brazil, Germany, and France (3-6). C. felis is apparently the main vector of this new rickettsial disease, and R. felis has been found in this flea in several countries, including the United States (2), Brazil (7), Spain (8), and Ethiopia (6). A reservoir of flea-borne spotted fever in the United States may be the opossum. Of major importance to the epidemiology of the above rickettsioses is the maintenance of R. typhi or R. felis in their hosts by transovarial transmission (9) and the fact that neither organism is lethal for fleas.

Bartonellae are gram-negative bacteria that cause various human diseases and have various arthropods, such as lice, ticks, and fleas, as vectors (10). Transmission to humans may also occur by scratches or bites from reservoir hosts, especially cats. Among the genus Bartonella, four species have been isolated from the blood of cats. Two of these species occur worldwide, B. henselae, the agent of cat-scratch disease, and B. clarridgeiae, which might be another agent of cat-scratch disease (11), and two have been reported only from the United States, B. koehlerae and B. bovis. The main vector of B. henselae infections in cats is most likely the cat flea (2), whereas the vectors of B. koehlerae and B. weissii are unknown. Detection of B. clarridgeiae in cat fleas by polymerase chain reaction (PCR) amplification has indicated the possible role of fleas as vectors of the organism (15). Cats are the reservoirs of the bacteria, and the prevalence of cats with B. henselae and B. clarridgeiae bacteremia ranges from 4% to 70%, according to the geographic location (15).

We describe experiments in which we used PCR amplification and DNA sequencing to detect Rickettsia, Bartonella, and Ehrlichia species in C. felis collected from various sites in France.

Materials and Methods

Source and Identification of Cat Fleas

Cat fleas (C. felis), identified according to current taxonomic keys (16), were obtained from various departments by the Veterinary School of Toulouse, located throughout France. Cat fleas were sent to our laboratory in sealed, preservative-free, plastic tubes at room temperature. To prevent contamination problems, as positive controls we used DNA from R. montanensis (ATCC VR-611) and Bartonella elizabethae F9251 (ATCC 49927), which react with the primer pairs we used in PCR but give sequences distinct from the species we were investigating. For negative controls, we used sterile water and human body lice reared in our laboratory; both negative controls were tested after every seventh cat-flea sample in our PCR.

DNA Extraction

Fleas were immersed for 5 min in a solution of 70% ethanol/0.2% iodine, washed for 5 min in sterile distilled water...
and crushed individually in sterile Eppendorf tubes with the tip of a sterile pipette. Their DNA was extracted by using the QIAamp Tissue Kit (QIAGEN, Hilden, Germany) according to the manufacturer’s instructions. This kit was also used to extract DNA from the human body lice reared in our laboratory under standard conditions and used as negative controls.

Detection of Bartonella spp., Rickettsia spp., and Anaplasmataceae

DNA extracts were amplified in two different runs with different target genes to confirm the results. In the first run we tested all the cat fleas by using genus-specific primers (Table 1) derived from the intergenic spacer region (its gene), the pap31 gene for Bartonella (19,20), the citrate synthase–encoding gene for Rickettsia (17), and the 16S RNA gene for Anaplasmataceae (21,22). A total volume of 2.5 µL of the extracted DNA was amplified in a 25-µL reaction mixture containing 12.5 pmol of each primer, 200 µM of dATP, dCTP, dGTP, and dTTP, and 1 U of Elongase in 1X PCR buffer with 0.8 µL of 25 mM MgCl2 (Life Technologies, Cergy Pontoise, France). PCR was carried out in a Peltier Thermal Cycler PTC-200 (MJ Research, Inc., Watertown, MA) with an initial 3-min denaturation step at 95°C, followed by 40 cycles of denaturation at 95°C (30 s), annealing at 50°C (30 s), and extension at 72°C (1 min). Amplification was completed by holding the reaction mixture at 68°C for 3 min to allow complete extension of the PCR products. PCR products were resolved by electrophoresis in 1% agarose gels, and when appropriately sized fragments were obtained, were identical to those of Bartonella.

The positive PCR products of the two runs for Bartonella, Rickettsia, and Wolbachia were sequenced by using the d-terminator cycle-sequencing ready reaction kit (PE Applied Biosystems, Les Ulis, France) according to the manufacturer’s protocol. Sequences obtained were compared with those in the GenBank DNA database by using the program BLAST (version 2.0, National Center for Biotechnology Information; available from: URL: http://www.ncbi.nlm.nih.gov).

Results

Overall, 309 cat fleas from 92 cats from all areas of France (north, west, east, and south) were tested. Almost two thirds (60/92; 65%) of the cats lived both outdoors and indoors, 20% lived predominantly outdoors, and 15% lived exclusively indoors. Our negative controls consistently failed to yield detectable PCR products, whereas our positive controls always gave expected PCR products. We found a total of 89 fleas (28.8%) that were infected: 25 were positive for R. felis (25/309; 8.1%) as determined by its gene or pap31 gene sequencing (Table 2). The sequences of the DNA amplicons we obtained were identical to those of R. felis (Genbank accession no. U33922), B. henselae (Genbank accession no. AF369527), B. clarridgeiae (Genbank accession no. AF312497), B.

koechlerae (GenBank accession no. AF312490), or B. quintana (GenBank accession no. AF368391). The Bartonella species we identified were B. henselae (9/89; 11.1%), B. claridgeiae (55/89; 67.9%), B. quintana (14/89; 17.3%), and B. koechlerae (3/89; 3.7%). Our results were confirmed by a second PCR with the Lightcycler and specific primers for the gltA gene for Bartonella and rOmpB for Rickettsia. Because the primers were species-specific, we were able to demonstrate that none of the fleas contained more than one Bartonella species. Seventeen fleas, however, contained R. felis and B. quintana (12 fleas) or B. claridgeiae (5 fleas) (Table 2). Lastly, in 55 fleas (17.8%) our Anaplasmataceae-specific primers amplified DNA with a sequence identical to that of Wolbachia pipiensis (Genbank accession no. U23709).

### Discussion

**Rickettsia** and *Bartonella* infections occur worldwide and may cause serious diseases in people. Most of these pathogenic bacteria are transmitted to people by arthropod vectors such as ticks, fleas, and lice, which are also involved in the maintenance of the bacteria. The detection of these pathogenic bacteria in their vector arthropods can be used in epidemiologic studies and control strategies (2). We tested cat fleas from around France for the presence of *Rickettsia*, *Bartonella*, and *Ehrlichia* species. We found DNA of *R. felis* and various *Bartonella* species in these fleas by using PCR with primers for different specific genes and sequencing to confirm our results. All our negative controls gave no PCR products, and all fleas that tested positive were also positive with other PCRs with different target genes and different techniques.

We report for the first time the presence of *R. felis* in cat fleas from France. This bacteria has been detected previously in wild cat fleas from various countries, including the United States (2), Ethiopia (6), and, very recently, Spain (8), and Brazil (7). Since *C. felis* has a worldwide distribution and infestation with these fleas is very common, some have assumed that *R. felis* and flea-borne spotted fever should occur worldwide. We found that 8.1% of fleas from domestic cats were infected with *R. felis*, suggesting that clinical cases in humans may be prevalent in France and probably in Europe. In the United States, the infection rates of fleas, as determined by PCR amplification, have been reported to vary from 43% to 93% (2). Since bacteria are maintained transovarially, *R. felis* may be used as a marker to follow changes in the infection rates over time (2). In people, clinical cases of flea-borne spotted fever have been reported in the United States (Texas) (3), Mexico (4), France, and Brazil (6), and, very recently, in Germany (5). Preliminary serologic results indicate that flea-borne spotted fever might occur in France (6), and we have now shown that fleas in France are infected with *R. felis*. The disease is probably more prevalent than expected, even if the risk of transmission by fleas is unknown. Cross-reactions in serologic testing for *R. felis* are unpredictable in our experience, and thus serologic tests for *R. felis* should be performed in patients suffering from fever of unknown origin. Our findings of *R. felis* in French fleas indicate, then, that *R. felis* should be used, along with other spotted fever group rickettsiae, in serologic tests on patients suspected of having a spotted fever group rickettsiosis.

To date, *B. henselae* is the only recognized agent of cat-scratch disease; epidemiologic studies have implicated cats, which remain bacteremic for months to years, as the major reservoirs of *B. henselae* (23,24). Its DNA has been amplified from fleas found on bacteremic cats, and transmission of *B. henselae* to cats by *C. felis* has been demonstrated (23,25,26). Flea infestation was found to be more common in bacteremic cats than in nonbacteremic cats. The prevalence of *B. henselae* in fleas in our study was 3%, whereas *B. henselae* has been isolated from the blood of 4% to 70% of cats, depending on location, cat population, and flea infestation rate but not depending on the infection rate of fleas on the cats or the seropositivity of the cats (15,25).

Our study has confirmed that *B. claridgeiae* may be detected in fleas, and we found a 17.8% prevalence in infected fleas, that is, 67.9% of all fleas positive for *Bartonella* by PCR. Until now, *B. henselae* was the most common species isolated from cats, and the prevalence of *B. claridgeiae* has ranged from 16% to 30% (25). *B. claridgeiae* is more prevalent in European cats than in American cats (25). The difference of recovery rate of *B. claridgeiae* in these studies may be explained by the fact that the number of bacteria in the blood of cats infected with *B. claridgeiae* is low (unpub. data) and because *B. claridgeiae* grows more slowly in culture (27). Also, freezing of whole blood improves the recovery rate of *B. claridgeiae* since bacteria are probably localized in erythrocytes (15).

We report, for the first time, the presence of *B. koechlerae* in cat fleas. This recently described species has only been reported in the blood of cats in the United States (12), and our findings support the idea that this bacteria might be transmitted by cat fleas, like other *Bartonella*, and that it has a worldwide distribution. The prevalence of this new *Bartonella* species in cats remains unknown and is probably underestimated because the bacteria are extremely fastidious and only grow on chocolate agar and not on heart infusion agar with rabbit blood, Columbia, or on sheep blood agar, which are currently widely used for the isolation of *Bartonella* (12).

We also report for the first time that cat fleas can contain *B. quintana*; this is surprising because, to date, the body louse
was the only known vector of this species, and people are the only known natural reservoirs. Previously, however, in two clinical reports of chronic adenopathy attributed to *B. quintana* infection, the only epidemiologic risk identified was the presence of infected cat fleas (28,29). The role of the cat flea as a potential vector of *B. quintana* and its related diseases needs to be clarified, and new investigations of patients in contact with cats and their fleas are indicated. Also, we have reported cases of endocarditis due to *B. quintana* for which no epidemiologic risks (alcoholism or homelessness) were found (30,31). These findings and the fact that *B. quintana* DNA sequences can be found in ticks (32) indicate that other arthropod vectors apart from lice may be involved in the epidemiology of *B. quintana* infections.

Coinfection of cats with *B. claridgeiae* and *B. henselae* has been reported, as has infection with the two different genotypes of *B. henselae*, Marseille and Houston (25,33). Recent reports suggest that interspecific competition between closely related rickettsiae may control rickettsial establishment in arthropods (dual infections in arthropod vectors are rare and have not yet been observed in individual fleas) (34). Fleas, however, feed intermittently on different hosts and thus may acquire multiple bacterial strains and pass these to their progeny transovarially (2). Our finding of *R. felis* with either *B. claridgeiae* or *B. quintana* in fleas suggests that dual infections may occur in humans infected by flea feces. We did not, however, find fleas infected with several species of *Bartonella* although cats may be bacteremic with two different species. We believe that the techniques we used should have been sensitive enough to detect such coinfections, and that competition between two *Bartonella* species may result in one species being eliminated and the flea becoming infected with the other *Bartonella* species. Further studies are indicated to confirm this possibility.

Finally, we report, for the first time, the presence of *W. pipientis* in fleas, which we found while seeking Ehrlichia using *Anaplasmataceae*-specific primers. This bacteria is known to be an endosymbiont of several arthropods, primarily insects, and it has a role in parthenogenesis (35). Any effects that it might have on fleas, however, are unknown.

In summary, our study has provided evidence that cat fleas are commonly infected by *R. felis* and *Bartonella* species in France. Further, we have shown for the first time that *B. quintana* may infect fleas. The description of *B. quintana*–related diseases in patients with histories of contact with fleas indicates the possibility that fleas may be vectors of the organism. Finally, we reported for the first time the presence of *B. koehlerae* outside the United States.

Acknowledgments

We thank Patrick Kelly for reviewing the manuscript.

Dr. Rolain is a microbiologist at the Unité des Rickettsies, the national reference center for rickettsiosis and World Health Organization collaborative center. The laboratory is primarily involved in the study of emerging and reemerging bacteria and arthropod-borne diseases.
