ABSTRACT

Sparsity regularized loss minimization problems play an important role in various fields including machine learning, data mining, and modern statistics. Proximal gradient descent method and coordinate descent method are the most popular approaches to solving the minimization problem. Although existing methods can achieve implicit model identification, aka support set identification, in a finite number of iterations, these methods still suffer from huge computational costs and memory burdens in high-dimensional scenarios. The reason is that the support set identification in these methods is implicit and thus cannot explicitly identify the low-complexity structure in practice, namely, they cannot discard useless coefficients of the associated features to achieve algorithmic acceleration via dimension reduction. To address this challenge, we propose a novel accelerated doubly stochastic gradient descent (ADSGD) method for sparsity regularized loss minimization problems, which can reduce the number of block iterations by eliminating inactive coefficients during the optimization process and eventually achieve faster explicit model identification and improve the algorithm efficiency. Theoretically, we first prove that ADSGD can achieve a linear convergence rate and lower overall computational complexity. More importantly, we prove that ADSGD can achieve a linear rate of explicit model identification. Numerically, experimental results on benchmark datasets confirm the efficiency of our proposed method.

CCS CONCEPTS

• Computing methodologies → Feature selection. Regularization.

1 INTRODUCTION

Many popular statistical learning models, such as Lasso [27], group Lasso [32], sparse logistic regression [29], Sparse-Group Lasso [26], elastic net [35], sparse Support Vector Machine (SVM) [34], etc. have been developed and achieved great success for both regression and classification tasks in machine learning, data mining, and modern statistics. Given design matrix $A \in \mathbb{R}^{n \times d}$ with $n$ observations and $d$ features, these models can be formulated as regularized loss minimization problems:

$$ \min_{x \in \mathbb{R}^d} \mathcal{P}(x) := \mathcal{F}(x) + \lambda \Omega(x), \quad (1) $$

where $\mathcal{F}(x) = \frac{1}{n} \sum_{i=1}^{n} f_i(a_i^\top x)$ is the data-fitting loss, $\Omega(x)$ is the block-separable regularizer that encourages the property of the model parameters, $\lambda$ is the regularization parameter, and $x$ is the model parameter. Let $\mathcal{G}$ be a partition of the coefficients, we have $\Omega(x) = \sum_{j \in \mathcal{G}} \Omega_j(x_{g_j}).$

Proximal gradient descent (PGD) method was proposed in [5, 16] to solve Problem (1). However, at each iteration, PGD requires gradient evaluation of all the samples, which is computationally expensive. To address this issue, stochastic proximal gradient (SPG) method is proposed in [8], which only relies on the gradient of a sample at each iteration. However, SPG only achieves a sublinear convergence rate due to the gradient variance introduced by random sampling. Further, proximal stochastic variance-reduced gradient methods, such as ProxSVRG [30] and ProxSAGA [7], were proposed to achieve a linear convergence rate for strongly convex functions.

On the other hand, coordinate descent method has received increasing attention due to its efficiency. Randomized block coordinate descent (RBCD) method is proposed in [23, 24], which only updates a single block of coordinate at each iteration. However, it is still expensive because the gradient evaluation at each iteration depends on all the data points. Further, doubly stochastic gradient methods are proposed in [6, 25]. Among them, [6], called stochastic randomized block coordinate descent (SRBCD), computes the partial derivative on one coordinate block with respect to a sample. However, SRBCD can only achieve a sublinear convergence rate due to the variance of stochastic gradients. Further, accelerated mini-batch randomized block coordinate descent (MRBCD) method [29, 33] was proposed to achieve a linear convergence rate by reducing the gradient variance.
Table 1: Comparison between existing methods and our ADSGD method. “Stochasticity” represents whether the method is stochastic on samples or coordinates.

| Method          | Stochasticity | Sample Scalability | Low Per-iteration Cost | Model Identification | Identification Rate |
|-----------------|---------------|--------------------|------------------------|----------------------|---------------------|
| PGD-type Method [16, 30] | ✓             | ✓                  | ✗                      | Implicit             | –                   |
| Screening [1, 10]         | ✗             | ✗                  | ✓                      | Explicit             | –                   |
| ADSGD (Ours)          | ✓             | ✓                  | ✓                      | Implicit & Explicit  | $O(\log(\frac{1}{\epsilon}))$ |

However, all the existing methods still suffer from huge computational costs and memory usage in the practical high-dimensional scenario. The reason is that these methods require the traversal of all the features and correspondingly the overall complexity increases linearly with feature size. The pleasant surprise is that the non-smooth regularizer usually promotes the model sparsity and thus the solution of Problem (1) has only a few non-zero coefficients, aka the support set. In high-dimensional problems, model identification, aka support set identification, is a key property that can be used to speed up the optimization. If we can find these non-zero features in advance, Problem (1) can be easily solved by restricted to the support set with a significant computational gain without any loss of accuracy.

Model identification can be achieved in two ways: implicit and explicit identification. In terms of the implicit model identification, PGD can identify the support set after a finite number of iterations $T$ [13–15], which means, for some finite $K > 0$, we have supp$(x^K) = \text{supp}(x^\star)$ holds for any $k > K$. Other popular variants of PGD [15, 21] also have such an implicit identification property. However, these results can only show the existence of $T$ and cannot give any useful estimate without the knowledge of $\theta^\star$ [13, 14], which makes it implicit and impossible to explicitly discard the coefficients that must be zero at the optimum in advance. In terms of the explicit model identification, screening can identify the zero coefficients and discard these features directly [1, 3, 10]. By achieving dimension reduction, the algorithm only needs to solve a sub-problem and save much useless computation. However, first, existing works [1, 3, 10, 18, 22] mainly focus on the existence of identification but fail to show how fast we can achieve explicit model identification. Besides, existing works on explicit model identification [19] are limited to the deterministic setting. Therefore, accelerating the model training by achieving fast explicit model identification is promising and sorely needed for high-dimensional problems in the stochastic setting.

To address the challenges above, in this paper, we propose a novel Accelerated Doubly Stochastic Gradient Descent (ADSGD) method for sparsity regularized loss minimization problems, which can significantly improve the training efficiency without any loss of accuracy. On the one hand, ADSGD computes the partial derivative on one coordinate block with respect to a mini-batch of samples to simultaneously enjoy the stochasticity on both samples and features and thus achieve a low per-iteration cost. On the other hand, ADSGD not only enjoys implicit model identification of the proximal gradient method, but also enjoys explicit model identification by eliminating the inactive features. Specifically, ADSGD has two loops. We first eliminate the inactive blocks at the main loop. Within the inner loop, we only estimate the gradient over a selected active block with a mini-batch of samples. To reduce the gradient variance, we adjust the estimated gradient with the exact gradient over the selected block. Theoretically, by addressing the difficulty of the uncertainty of double stochasticity, we establish the analysis for the convergence of ADSGD. Moreover, by linking the sub-optimality gap and duality gap, we provide theoretical analysis for fast explicit model identification. Finally, based on the results of the convergence and explicit model identification ability, we establish the theoretical analysis of the overall complexity of ADSGD. Empirical results show that ADSGD can achieve a significant computational gain than existing methods. Both the theoretical and the experimental results confirm the superiority of our method. Table 1 summarizes the advantages of our ADSGD over existing methods.

Contributions. We summarize the main contributions of this paper as follows:

- We propose a novel accelerated doubly stochastic gradient descent method for generalized sparsity regularized problems with lower overall complexity and faster explicit model identification rate. To the best of our knowledge, this is the first work of doubly stochastic gradient method to achieve a linear model identification rate.
- We derive rigorous theoretical analysis for our ADSGD method for both strongly and nonstrongly convex functions. For strongly convex function, ADSGD can achieve a linear convergence rate $O(\log(\frac{1}{\epsilon}))$ and reduce the per-iteration cost from $O(d)$ to $O(s)$ where $s \ll d$, which improves existing methods with a lower overall complexity $O(s(n+\frac{1}{d})\log(\frac{1}{\epsilon}))$. For nonstrongly convex function, ADSGD can also achieve a lower overall complexity $O(s(n+\frac{1}{d})\log(\frac{1}{\epsilon}))$.
- We provide the theoretical guarantee of the iteration number $T$ to achieve explicit model identification. We rigorously prove our ADSGD algorithm can achieve the explicit model identification at a linear rate $O(\log(\frac{1}{\epsilon}))$.

2 PRELIMINARY

2.1 Notations and Background

For norm $\Omega(\cdot)$, $\Omega^D(\cdot)$ is the dual norm and defined as $\Omega^D(u) = \max_{z \in \mathbb{R}^d} \langle z, u \rangle$ for any $u \in \mathbb{R}^d$ if $z \in \mathbb{R}^d$. Denote $\theta$ as the dual solution and $\Delta_A$ as the feasible space of $\theta$, the dual formulation $D(\theta)$ of Problem (1) can be written as:

$$
\max_{\theta \in \Delta_A} D(\theta) := -\frac{1}{n} \sum_{i=1}^n f_i^\star (-\theta_i). \tag{2}
$$

The dual $D(\theta)$ is strongly concave for Lipschitz gradient continuous $F(x)$ (see Proposition 3.2 in [11]).
For Problem (1), based on the subdifferential [12, 17], Fermat’s conditions (see [4] for Proposition 26.1) holds as:

\[
\frac{1}{n} A_j^T \theta^* \in \lambda \partial \Omega_j(x^*_j).
\] (3)

The optimality conditions of Problem (1) can be read from (3) as:

\[
\frac{1}{n} \Omega_j^D(A_j^T \theta^*) = \lambda, \quad \text{if } x^*_j \neq 0;
\] (4)

\[
\frac{1}{n} \Omega_j^D(A_j^T \theta^*) \leq \lambda, \quad \text{if } x^*_j = 0.
\] (5)

2.2 Definitions and Assumptions

One key property of our method is to achieve explicit model identification, which means we can explicitly find the Equicorrelation Set in Definition 1 of the solution.

**Definition 1. (Equicorrelation Set (see [28]))** Suppose \( \theta^* \) is the dual optimal, the equicorrelation set is defined as

\[
S^* = \{ j \in \{1, 2, \ldots, q \} : \frac{1}{n} \Omega_j^D(A_j^T \theta^*) = \lambda \}. \] (6)

**Assumption 1.** Given the partition \( \{ G_1, \ldots, G_q \} \), all \( \nabla_{G_j} f_i(x) = \{ \nabla f_i(x) \}_{G_j} \) are block-wise Lipschitz continuous with constant \( L_i \), which means that for any \( x \) and \( x' \), there exists a constant \( L = \max_i L_i \), we have

\[
\| \nabla f_i(x) - \nabla f_i(x') \| \leq L \| x - x' \|, \] (7)

**Assumption 2.** \( f(x) \) and \( \Omega(x) \) are proper, convex and lower-semicontinuous.

Assumptions 1 and 2 are commonly used in the convergence analysis of the RBCD method [29, 33], which are standard and satisfied by many regularized loss minimization problems. Assumption 1 implies that there exists a constant \( T \leq qL \), for any \( x \) and \( x' \), we have

\[
\| \nabla f_i(x) - \nabla f_i(x') \| \leq T \| x - x' \|, \] (8)

i.e., \( \nabla f_i(x) \) is Lipschitz continuous with constant \( T \).

3 PROPOSED METHOD

In this section, we will introduce the accelerated doubly stochastic gradient descent (ADSGD) method with discussions.

To achieve the model identification, a naive implementation of the ADSGD method is summarized in Algorithm 1. The ADSGD algorithm can reduce the size of the original optimization problem and the variables during the training process. Thus, the latter problem has a smaller size and fewer variables for training, which is a sub-problem of the problem from the previous step, but generates the same optimal solution.

We denote the original problem as \( P_0 \) and subsequent subproblem as \( P_{k-1} \) at the \( k \)-th iteration in the main loop of ADSGD. Moreover, we define the active set at the \( k \)-th iteration of the main loop as \( S_{k-1} \). Thus, in the main loop of ADSGD, we compute \( \theta_{k-1} \) with the active set \( S_{k-1} \) from the previous iteration as

\[
\theta_{k-1} = \frac{-\nabla F(\hat{x}_{k-1})}{\max(1, \Omega_{S_{k-1}}^{D}(A_{S_{k-1}}^T \nabla F(\hat{x}_{k-1}))/\lambda)}.
\] (9)

Then we compute the intermediate duality gap

\[
\text{Gap}(\hat{x}_{k-1}, \theta_{k-1}) := P_{k-1}(\hat{x}_{k-1}) - D_{k-1}(\theta_{k-1}).
\] (10)

for the screening test. In step 6, we obtain new active set \( S_k \) from \( S_{k-1} \) by the screening conducted on all \( j \in S_{k-1} \) as

\[
\frac{1}{n} \Omega_j^D(A_j^T \theta_{k-1}) + \frac{1}{n} \Omega_j^D(A_j) \xi^{k-1} < \lambda \Rightarrow \hat{x}^*_j = 0,
\] (11)

where the safe region is chosen as spheres \( R = B(\theta_{k-1}, r^{k-1}) \)

[1, 18].

With obtained active set \( S_k \), we update the design matrix \( A \) and the related parameter variables \( x^0, x \) in step 7. In the inner loop, we conduct all the operations on \( S_k \). To make the algorithm scale well with the sample size, we only randomly sample a mini-batch \( I \in \{1, 2, \ldots, n\} \) of samples at each iteration to evaluate the gradients.

**Algorithm 1** The ADSGD method

**Input:** \( \hat{x}_0 \).

1. for \( k = 1, 2, \ldots \) do
   2. \( \hat{x}_{k-1} = \hat{x}_{k-1} \).
   3. \( x^0_{k-1} = \hat{x}_{k-1} \).
   4. Compute \( \theta_{k-1} \) by (9).
   5. \( r^{k-1} = \sqrt{2T \text{ Gap}(x^0_{k-1}, \theta_{k-1})} \).
   6. Update \( S_k \subset S_{k-1} \) by (11).
   7. Update \( A_{S_k}, x^0_{S_k}, \hat{x}_{S_k} \) with \( S_k \).
   8. for \( t = 1, 2, \ldots, \frac{m_q}{q} \) do
      9. Randomly pick \( I \in \{1, 2, \ldots, n\} \).
      10. \( x_{k}^t = \text{prox}_{\eta \lambda}(x_{k}^{t-1} - \eta \nabla f_I(x_{k}^{t-1})) \).
   11. end for
   12. \( \hat{x}_{k} = \frac{1}{m_q} \sum_{t=1}^{m_q} x_{k}^t \).
   13. end for

**Output:** Coefficient \( \hat{x}_k \).

**Property 1.** Let \( \hat{x}_j \) be the \( j \)-th block of \( \hat{x} \) in Algorithm 1, \( \forall j \in \{1, 2, \ldots, q\} \), \( \hat{x}_j \), discarded by ADSGD is guaranteed to be 0 at the optimum.

**Remark 1.** Property 1 shows that ADSGD is guaranteed to be safe not only for the current iteration but also for the whole training process. The safety of the screening is the foundation of the analysis of convergence and explicit model identification rate in the following part.

**Remark 2.** Property 1 also shows that discarding inactive variables can either decrease or make no changes to the objective function.

**Doubly Stochastic Gradient Update.** Since ADSGD is only singly stochastic on samples, the gradient evaluation is still expensive because it depends on all the coordinates at each iteration. Thus, we randomly select a coordinate block \( j \) from \( S_k \) to enjoy the stochasticity on features. Specifically, ADSGD only computes the partial derivative \( \nabla_{G_j} f_I(x_{k}^{t-1}) \) on one coordinate block with respect to a sample each time, which yields a much lower per-iteration computational cost. The proximal step is computed as:

\[
\text{prox}_{\eta \lambda}(x_{j}^t) = \arg \min_{x_{j}} \frac{1}{2\eta} ||x_{j}^t - x_{j}||^2 + \lambda \Omega_j(x_{j}).
\] (12)

Therefore, ADSGD is doubly stochastic and can scale well with both the sample size and feature size.
Algorithm 2 The ADSGD method

Input: $\hat{x}_0$.
1. for $k = 1, 2, \ldots$ do
2. $\tilde{x}_{k-1} = \hat{x}_{k-1}$.
3. $\mu_k = \nabla f_{I_k}(\tilde{x}_{k-1}^\top) - \nabla f_{I_k}(\tilde{x}_k) + \mu_k g_{I_k} k$.
4. $x_{k-1}^0 = \tilde{x}_{k-1}$.
5. Compute $\hat{\phi}_{k-1}$ by (9).
6. $\tilde{x}_{k} = \frac{\tilde{x}_{k-1}}{\sqrt{2}} G_{k-1} - \frac{\tilde{x}_{k-1}}{\sqrt{2}} G_{k-1}$.
7. Update $S_k \subset S_{k-1}$ by (11).
8. Update $A_{S_k}, x_{k, t}^k, \hat{x}_k, \mu_k$ with $S_k$.
9. for $t = 1, 2, \ldots, \frac{m_k}{\eta}$ do
10. Randomly pick $I \subset \{1, 2, \ldots, n\}$.
11. Randomly pick $j$ from $S_k$.
12. $\theta_k = \arg \min_{\theta} (\tilde{x}_{k}^\top) - \eta \theta_g_{I_k}$.
13. $x_{k, t}^k = \theta_k g_{I_k} - \eta \mu_k$.
14. end for
15. $\hat{x}_k = \frac{1}{m_k} \sum_{t=1}^{m_k} x_{k, t}^k$.
16. end for
Output: Coefficient $\hat{x}_k$.

Variance Reduction on the Selected Blocks. However, the gradient variance introduced by stochastic sampling does not converge to zero. Hence, a decreasing step size is required to ensure the convergence. In that case, even for strongly convex functions, we can only obtain a sublinear convergence rate. Thanks to the full gradient we computed in step 3, we can adjust the partial gradient estimation over the selected block $g_{I_k}$ to reduce the gradient variance with almost no additional computational costs as:

$$\mu_k = \nabla g_{I_k} f_{I_k}(x_{k-1}^\top) - \nabla g_{I_k} f_{I_k}(\tilde{x}_k) + \mu_k g_{I_k} k.$$  \hspace{1cm} (13)

It can guarantee that the variance of stochastic gradients asymptotically goes to zero. Thus, a constant step size can be used to achieve a linear convergence rate if $P$ is strongly convex.

The algorithmic framework of the ADSGD method is presented in Algorithm 2. ADSGD can identify inactive blocks and thus only active blocks are updated in the inner loop, which can make more progress for training than conduct useless updates for inactive blocks. Thus, fewer inner loops are required for each main loop and correspondingly huge computational time is saved.

Suppose we have $q_k$ active blocks for the inner loop at the $k$-th iteration, we only do $m_k = \frac{m_k}{q_k}$ iterations in the inner loop for the current outer iteration, which means the number of the inner loops continues decreasing in our algorithm. The output for each iteration is the average result of the inner loops. As the algorithm converges, the duality gap converges to zero and thus (11) can eliminate more inactive blocks and thus save the computational costs to a large extent.

Remarkably, the key step of the screening in Algorithm 2 is the computation of the intermediate duality gap, which only imposes extra $O(q_k)$ costs to the original algorithm at the $k$-th iteration. Note the extra complexity of screening is much less than $O(d)$ in practice, which would not affect the complexity analysis of the algorithm. Further, at the $k$-th iteration, our Algorithm 2 only requires the computation over $S_k$, which could be much smaller than the original model over the full parameter set. Hence, in high-dimensional regularized problems, the computation costs are promising to be effectively reduced with the constantly decreasing active set $S_k$.

On the one hand, ADSGD enjoys the implicit model identification of the proximal gradient method. On the other hand, discarding the inactive variables can further speed up the identification rate. Thus, ADSGD is promising to achieve a fast identification rate by simultaneously enjoying the implicit and explicit model identification to yield a lower per-iteration cost.

4 THEORETICAL ANALYSIS

In this section, we first give several useful lemmas and then provide theoretical analysis on the convergence, explicit model identification, and overall complexity. Detailed proof can be found in [2].

4.1 Useful Lemmas

**Lemma 1.** Define $v_f = \frac{1}{|I|} \sum_{i \in I} (\nabla f_i(x_i^{t-1}) - \nabla f_i(\tilde{x})) + \nabla f(\tilde{x})$, $\bar{x} = \frac{1}{|I|} \sum_{i \in I} \nabla f_i(x_i^{t-1})$, $\bar{x} = \frac{1}{|I|} \sum_{i \in I} \nabla f_i(x_i^{t-1} - \eta v_f)$ and $\hat{x} = \arg \min_{x} \frac{1}{2q} \|x - \tilde{x}\|^2 + \Omega(x)$, we have

$$E_f (v_f - \nabla f(x^{t-1})) (x^t - \tilde{x}) \leq \eta E_f \|v_f - \nabla f(x^{t-1})\|^2.$$  \hspace{1cm} (14)

**Proof.** We can first prove

$$E_f (v_f - \nabla f(x^{t-1})) (x^t - \tilde{x} - \bar{x}) = E_f [(v_f - \nabla f(x^{t-1})) (x^t - \bar{x})]$$

and then prove

$$E_f (v_f - \nabla f(x^{t-1})) (x^t - \tilde{x}) = \eta E_f \|v_f - \nabla f(x^{t-1})\|^2.$$  \hspace{1cm} (15)

to obtain Lemma 1 by using Cauchy-Schwarz inequality and the non-expansiveness of the proximal operator.

**Lemma 2.** (See [30]) Define $v_i = \nabla f_i(x_i^{t-1}) - \nabla f_i(\tilde{x}) + \nabla f(\tilde{x})$, conditioning on $x_i^{t-1}$, we have

$$E_i v_i = \nabla f(x^{t-1}),$$

and

$$E_i \|v_i - \nabla f(x^{t-1})\|^2 \leq 4T \|P(x^{t-1}) - P(x^t) - P(\tilde{x})\|. $$

**Lemma 3.** (See [33]) Define $\delta = (\tilde{x} - x)/\eta$ and $\eta g_j = (\tilde{x} - x)/\eta$ where $\tilde{x} = \arg \min_{x} \frac{1}{2q} \|x - x_0\|^2 + \Omega(x)$, we have

$$E_j \delta g_j = \delta/q \quad \text{and} \quad E_j \|\delta g_j\| = \|\delta\|^2.$$  \hspace{1cm} (16)

Moreover, taking $\eta \leq \frac{1}{q}$, we have

$$E_j [(x - x^\top) \delta g_j + \frac{\eta}{2} \delta g_j \delta g_j] \leq \frac{1}{q} P(x) + \frac{1}{q} P(\bar{x}) - E_j P(\tilde{x} g_j)$$

$$+ \frac{1}{q} (v - \nabla f(x^t))(x^t - \tilde{x}),$$

where $x^t = \arg \min_{x} P(x)$.

4.2 Strongly Convex Functions

We establish the theoretical analysis of ADSGD for strongly convex $f$ here.
4.2.1 Convergence Results

Lemma 4. Suppose $\hat{x}_k$ and $\check{x}_k$ are generated from the $k$-th iteration of the main loop in Algorithm 2 and let $|I| \geq \frac{T}{L}$ and $\eta < \frac{1}{4T}$, we have

$$E_P k(\hat{x}_k) - P k(\check{x}_k) \leq \rho_{k} [P k(\hat{x}_k) - P k(\check{x}_k)],$$

(17)

where $\rho_{k} = \frac{q_k}{\mu(1-4L\eta)m_k} + \frac{4\eta m_k + 1}{(1-4L\eta)m_k}$. We can choose $|I| = \frac{T}{L}$, $\eta = \frac{1}{16T}$, and $m = \frac{65q_T}{\mu}$ to make $\rho_{k} < \frac{1}{2}$.

Proof. At the $k$-th iteration of the main loop, all the updates in the inner loop are conducted on sub-problem $P_k$ with the active set $S_k$. At the $t$-th iteration of the inner loop for the $k$-th main loop, we randomly sample a mini-batch $I$ and $G_t \subseteq S_t$.

Define $v_t = \nabla f_i(x_{k-1}^t) - \nabla f_i(\check{x}_k) + \nabla f^T(\check{x}_k)$, based on Lemma 2, conditioning on $x_{k-1}^t$, we have

$$E_{v_t} = \nabla f^T(x_{k-1}^t),$$

and

$$E_{v_t} = \nabla f^T(x_{k-1}^t),$$

$$E_{v_t} = \nabla f^T(x_{k-1}^t),$$

$$E_{v_t} = \nabla f^T(x_{k-1}^t),$$

$$E_{v_t} = \nabla f^T(x_{k-1}^t),$$

and

$$\|v_t\| - \nabla f^T(x_{k-1}^t) \leq \frac{1}{|I|} \sum_{i \in I} \| \nabla f_i(x_{k-1}^t) \|,$$

(20)

Moreover, taking $\eta \leq \frac{1}{T}$, we have

$$\frac{1}{|I|} \sum_{i \in I} \| \nabla f_i(x_{k-1}^t) \| = \eta \frac{1}{T} \sum_{i \in I} \| \nabla f_i(x_{k-1}^t) \|.$$
We can choose $|I| = \frac{r}{r}$, $\eta = \frac{e_{\log}}{2\eta}$, and $m = \frac{e_{\log} k}{\mu}$ to make $\rho < \frac{2}{3}$.

**Proof.** Considering each sub-problem $P_k$, based on Lemma 4, for each main loop, we have

$$E_P(\hat{x}_k) - P_k(\hat{x}_k) \leq \rho \left[ P_k(\hat{x}_k) - P_k(x_k^*) \right] .$$

(33)

Since the eliminating in the ADSDG algorithm is safe, the optimal solution of all the sub-problems are the same. Thus, we have

$$P_k(x_k^*) = P_{k-1}(x_{k-1}^*) .$$

(34)

Then, the coefficients eliminated at the $k$-th iteration of the main loop must be zeroes at the optimal, which means the eliminating stage at the $k$-th iteration of the main loop actually minimizes the sub-problem $P_{k-1}$ over the eliminated variables. Thus, we have

$$P_k(\hat{x}_k) \leq P_{k-1}(\hat{x}_{k-1}) .$$

Moreover, considering $P_{k-1}(\hat{x}_{k-1}) = P_{k-1}(\hat{x}_{k-1})$, we have

$$P_k(\hat{x}_k) \leq P_{k-1}(\hat{x}_{k-1}) .$$

(35)

Combining above, we have

$$E_P(\hat{x}_k) - P_k(\hat{x}_k) \leq \rho \left[ P_k(\hat{x}_k) - P_k(x_k^*) \right] .$$

(36)

We can choose $|I| = \frac{r}{r}$, $\eta = \frac{e_{\log}}{2\eta}$, and $m = \frac{e_{\log} k}{\mu}$ to make $\forall k, \rho_k < \frac{2}{3}$.

Thus, $\exists \rho < \frac{2}{3}$, applying the above inequality recursively, we obtain

$$E_P(\hat{x}_k) - P_k(\hat{x}_k) \leq \rho^k \left[ P_0(x_k^*) - P_0(x_k^*) \right] .$$

(37)

From (34), we have

$$P_k(x_k^*) = P_{k-1}(x_{k-1}^*) = \cdots = P_0(x_k^*) .$$

(38)

Note $P_0 = P$ and $S_0$ is the universe set for all the variables blocks, we have

$$E_P(\hat{x}_k) - P_k(x^*) \leq \rho^k \left[ P(\hat{x}) - P(x^*) \right] ,$$

(39)

which completes the proof.

**Remark 4.** Theorem 1 shows that ADSDG converges linearly to the optimum with the convergence rate $O(\log \frac{1}{\rho})$.

4.2.2 *Explicit Model Identification.*

**Lemma 5.** $\lim_{k \rightarrow \infty} \theta_k = \theta^*$ if $\lim_{k \rightarrow \infty} \hat{x}_k = x^*$.

**Proof.** Define $\alpha_k = \max \left\{ 1, \Omega^D A_S^T \nabla F(\hat{x}_k) / \lambda \right\}$. We have

$$\left\| \theta_k^{*} - \theta^* \right\|_2 \leq \left\| \frac{\nabla F(\hat{x}_k)}{\alpha_k} - \frac{\nabla F(x^*)}{\lambda} \right\|_2 ,$$

(40)

$$\leq 1 - \frac{\alpha_k}{\lambda} \left\| \frac{\nabla F(\hat{x}_k)}{\lambda} \right\|_2 + \left\| \frac{\nabla F(\hat{x}_k)}{\lambda} - \frac{\nabla F(x^*)}{\lambda} \right\|_2 .$$

Considering the right term, if $\lim_{k \rightarrow \infty} \hat{x}_k = \hat{x}^*$, we have

$$\alpha_k \rightarrow \max \left\{ 1, \Omega^D \left( A_S^T \nabla F(x^*) \right) / \lambda \right\} = 1,$$

and

$$\left\| \frac{\nabla F(\hat{x}_k)}{\lambda} - \frac{\nabla F(x^*)}{\lambda} \right\|_2 \rightarrow 0 .$$

Thus, the right term converges to zero, which completes the proof.

**Remark 5.** Lemma 5 shows the convergence of the dual solution is guaranteed by the convergence of the primal solution.

**Lemma 6.** $\exists u \in \partial D^P(A_S^T \theta_k)$, for all $s \in [0, 1]$, we have

$$P_k(\hat{x}_k) - P(x^*) \geq s \operatorname{Gap}(\hat{x}_k, \theta_k) - \frac{T^2}{2} \left\| A_S(u - \hat{x}_k) \right\|^2 .$$

(41)

**Proof.** From the smoothness of $F$, we have

$$F(\hat{x}_k) - F(\hat{x}_k + s(\hat{x}_k - \theta_k)) \geq -s \langle \nabla F(\hat{x}_k), A_S(u - \hat{x}_k) \rangle - \frac{s^2 T}{2} \left\| A_S(u - \hat{x}_k) \right\|^2 .$$

(42)

By the convexity of $\Omega$, we have

$$\Omega(\hat{x}_k) - \Omega(\hat{x}_k + s(\hat{x}_k - \theta_k)) \geq s \langle \Omega(\hat{x}_k) - \Omega(\theta_k) \rangle .$$

(43)

Moreover, we have

$$\Omega(\hat{x}_k) - \Omega(\theta_k) = \frac{1}{2} \left( \Omega(\hat{x}_k) - \Omega(\theta_k) \right) + \langle \nabla F(\hat{x}_k), A_S(\hat{x}_k - \theta_k) \rangle + \langle \nabla F(\hat{x}_k), A_S \hat{x}_k \rangle - \langle \nabla F(\hat{x}_k), A_S \theta_k \rangle + \langle \nabla F(\hat{x}_k), \hat{x}_k \rangle - \langle \nabla F(\hat{x}_k), \theta_k \rangle .$$

(44)

$$= \frac{1}{2} \left( \Omega(\hat{x}_k) - \Omega(\theta_k) \right) + \langle \nabla F(\hat{x}_k), A_S \hat{x}_k \rangle + \langle \nabla F(\hat{x}_k), \hat{x}_k \rangle - \langle \nabla F(\hat{x}_k), \theta_k \rangle .$$

(45)

$$= \text{Gap}(\hat{x}_k, \theta_k),$$

(46)

where the first equality comes from

$$\Omega(u) = (u, A_S^T \theta_k) - \Omega^D (A_S^T \theta_k) ,$$

and the third equality comes from

$$F(\hat{x}_k) = \langle \nabla F(\hat{x}_k), A_S \hat{x}_k \rangle \rightarrow -\langle \theta_k, \theta_k \rangle .$$

Therefore, for any $\hat{x}_k$ and $u$, we have

$$P_k(\hat{x}_k) - P(x^*) \geq \text{Gap}(\hat{x}_k, \theta_k) - \frac{T^2}{2} \left\| A_S(u - \hat{x}_k) \right\|^2 .$$

(47)

$$\geq \text{Gap}(\hat{x}_k, \theta_k) - \frac{T^2}{2} \left\| A_S(u - \hat{x}_k) \right\|^2 .$$

(48)

$$= \Omega(\hat{x}_k) - \Omega(\hat{x}_k + s(\hat{x}_k - \theta_k)) + \Omega(\hat{x}_k) - \Omega(\hat{x}_k + s(\hat{x}_k - \theta_k)) .$$

(49)

where the second equality comes from (42) and (43), which completes the proof.

**Remark 6.** The difficulty to analyze the model identification rate of ADSDG is that the screening is conducted on the duality gap while the convergence of the algorithm is based on the sub-optimality gap. Note the sub-optimality gap at the $k$-th iteration of the main loop is computed as $P_k(\hat{x}_k) - P(x^*)$, Lemma 6 links the sub-optimality gap and the duality gap at the $k$-th iteration.

**Theorem 2.** Define $\Delta_j = \frac{n \Delta_j}{\Omega^D (A_j^T \theta^*)}$, denote $\sigma_j^2$ as the spectral norm of $A$, suppose $\Omega$ has a bounded support within a ball of radius $M$, given any $\gamma \in (0, 1)$, any block that $j \notin S^*$ are correctly identified by ADSDG at iteration $\log \frac{1}{\rho} \left( \frac{1}{\epsilon_j} \right)$ with at least probability $1 - \gamma$ where $\rho$ is from Theorem 1 and $\epsilon_j = \frac{1}{\sqrt{n}} \frac{\rho \sigma_j^2}{\sigma_j^2}$, then

$$\frac{1}{\rho} \sigma_j^2 (P_k(x^*) - P(x^*)) \geq \frac{1}{\rho} \sigma_j^2 (P_k(x^*) - P(x^*)).$$

**Proof.** Based on the screening condition, any variable block $j$ can be identified at the $k$-th iteration when

$$\frac{1}{n} \sum_{j \in S^*} \left( \frac{1}{n} \Omega^D (A_j^T \theta^*) \right)^2 \leq \frac{1}{n} \Omega^D (A_j^T \theta^*) + \frac{2 n}{\rho} \Omega^D (A_j^T \theta^*) \leq \frac{1}{n} \Omega^D (A_j^T \theta^*) \leq \frac{1}{n} \Omega^D (A_j^T \theta^*) \leq \Delta_j .$$

Thus, we have that variable block $j$ can be identified when

$$\frac{n}{\rho} \sigma_j^2 (P_k(x^*) - P(x^*)) \leq \Delta_j .$$

(50)
Considering \( \hat{x}_k = \hat{x}_k \) and \( r^k = \sqrt{2T} \text{Gap}(\hat{x}_k, \theta_k) \), we have that any variable block \( j \) can be identified at the \( k \)-th iteration when

\[
\text{Gap}(\hat{x}_k, \theta_k) < \frac{\Delta_j^2}{2T}.
\]  

(51)

For \( u_k \in \partial D\left(A_j^2, \theta_k\right) \), considering \( \Omega \) has a bounded support within a ball of radius \( M \), we have

\[
\|A(u_k - \hat{x}_k)\| \leq 2\sigma_M M.
\]

Based on Lemma 6, we have

\[
\text{Gap}(\hat{x}_k, \theta_k) \leq \frac{1}{s}(\mathcal{P}_k(\hat{x}_k) - \mathcal{P}(x^*)) + 2T\sigma_M^2 s.
\]

Minimizing the right term over \( s \), we have

\[
\text{Gap}(\hat{x}_k, \theta_k) \leq \sqrt{8T\sigma_M^2 M^2(\mathcal{P}_k(\hat{x}_k) - \mathcal{P}(x^*))}.
\]  

(52)

Thus, we can make

\[
\sqrt{8T\sigma_M^2 M^2(\mathcal{P}_k(\hat{x}_k) - \mathcal{P}(x^*))} \leq \frac{\Delta_j^2}{s}.
\]  

(53)

to ensure the screening condition (51) holds. Since (53) can be reformulated as

\[
\mathcal{P}_k(\hat{x}_k) - \mathcal{P}(x^*) \leq \frac{1}{32} \frac{\Delta_j^4}{T^3\sigma_M^2 M^2},
\]

if \( \exists k \in \mathbb{N}^+ \), we have (54) hold, we can ensure the screening condition hold at the \( k \)-iteration.

From Theorem 1, we have

\[
\mathbb{E}\mathcal{P}_k(\hat{x}_k) - \mathcal{P}(x^*) \leq \rho^k [\mathcal{P}(\hat{x}) - \mathcal{P}(x^*)].
\]  

(55)

Thus, if we let \( (\mathcal{P}(\hat{x}) - \mathcal{P}(x^*))\rho^k \leq \frac{1}{32} \frac{\Delta_j^4}{T^3\sigma_M^2 M^2} \), we have

\[
\mathbb{E}\mathcal{P}_k(\hat{x}_k) - \mathcal{P}(x^*) \leq \frac{1}{32} \frac{\Delta_j^4}{T^3\sigma_M^2 M^2}.
\]  

(56)

By Markov inequality and Theorem 1, we have

\[
\mathbb{P}\left(\mathcal{P}_k(\hat{x}_k) - \mathcal{P}(x^*) \geq \frac{1}{32} \frac{\Delta_j^4}{T^3\sigma_M^2 M^2} \right) \leq \frac{32T^3\sigma_M^2 M^2}{\Delta_j^4} \mathbb{E}\mathcal{P}_k(\hat{x}_k) - \mathcal{P}(x^*))
\]

\[
\leq \frac{32T^3\sigma_M^2 M^2}{\Delta_j^4} \rho^k [\mathcal{P}(\hat{x}_k) - \mathcal{P}(x^*)].
\]

(57)

Denote \( e_j = \frac{1}{32} \frac{\Delta_j^4}{T^3\sigma_M^2 M^2(\mathcal{P}(\hat{x}_k) - \mathcal{P}(x^*))} \), if we choose \( k \geq \log \rho (\frac{1}{e_j}) \), we have

\[
\mathbb{P}\left(\mathcal{P}_k(\hat{x}_k) - \mathcal{P}(x^*) \geq \frac{1}{32} \frac{\Delta_j^4}{T^3\sigma_M^2 M^2} \right) \leq \frac{32T^3\sigma_M^2 M^2}{\Delta_j^4} e_j [\mathcal{P}(\hat{x}_k) - \mathcal{P}(x^*)] = \gamma.
\]  

(59)

Thus, for \( k \geq \log \rho (\frac{1}{e_j}) \), we have

\[
\mathcal{P}_k(\hat{x}_k) - \mathcal{P}(x^*) \leq \frac{1}{32} \frac{\Delta_j^4}{T^3\sigma_M^2 M^2}.
\]  

(60)

with at least probability \( 1 - \gamma \), which means any variable that \( j \not\in S^* \) are correctly detected and successfully eliminated by the ADSGD algorithm at iteration \( \log \frac{1}{\rho} (\frac{1}{e_j}) \) with at least probability \( 1 - \gamma \), which completes the proof.

\[
\square
\]

\[
\text{Remark 7. Theorem 2 shows that the equicorrelation set } S^* \text{ can be identified by ADSGD at a linear rate } O(\log \rho (\frac{1}{e_j})).
\]

with at least probability \( 1 - \gamma \). We use the Lipschitzing trick in [9] to restrict the function \( \Omega \) within a bounded support.

4.2.3 Overall Complexity.

\[
\text{Corollary 1. Suppose the size of the active features in set } S_k \text{ is } d_k \text{ and } d^* \text{ is the size of the active features in } S^*, \text{ so any } \gamma \in (0, 1), \text{ let } K_m = O(\log \rho (\frac{1}{e_j})), \text{ we have } d_k \text{ is decreasing and } d_{kr} \text{ equals to } d^* \text{ with at least probability } 1 - \gamma.
\]

Define \( s = \frac{1}{K_m} \sum_{k=1}^{K_m} d_k \) where \( K_m = O(\log \rho (\frac{1}{e_j})) \), the overall complexity of ADSGD is \( O(\rho s) \).

\[
\text{Proof. The first part of Corollary 1 is the direct result of Theorem 2. For the second part, Theorem 1 shows that the ADSGD method converges to the optimal with the convergence rate } O(\log \rho (\frac{1}{e_j})).
\]

For each main loop, the algorithm runs \( m_k \) inner loops. Thus, since \( m = \frac{d_l q}{\rho} \) and \( m_k = \frac{m q_k}{\rho} \), the ADSGD algorithm takes \( O(\rho \frac{d_l q}{\rho}) \) iterations to achieve \( \epsilon \) error.

For the computational complexity, considering the \( k \)-th iteration of the main loop, the algorithm is solving the sub-problem \( \mathcal{P}_k \) and the complexity of the outer loop is \( O(n d_k) \). Within the inner loop, the complexity of each iteration is \( \frac{d_k}{q_k} \). Thus, the complexity of the inner loop is \( m_k \frac{d_k}{q_k} \). Let \( |I| = \frac{I}{\rho} \), define \( s = \frac{1}{K_m} \sum_{k=1}^{K_m} d_k \) where \( K_m = O(\log \rho (\frac{1}{e_j})) \), the overall complexity for the ADSGD algorithm is \( O(n + \frac{1}{\rho} s \log \rho (\frac{1}{e_j})) \), which completes the proof.

\[
\square
\]

\[
\text{Remark 8. Please note the difference between the number of features as } d_k \text{ and the number of blocks as } q_k \text{ at the } k \text{-th iteration. In the high-dimensional setting, we have } d^* \ll d \text{ and } s \ll d. \text{ Thus, Corollary 1 shows that ADSGD can simultaneously achieve linear convergence rate and low per-iteration cost, which improves prox-SVRG and MRBCD with the overall complexity } O(n + \frac{1}{\rho} d \log \rho (\frac{1}{e_j})) \text{ at a large extent in practice.}
\]

4.3 Nonstrongly Convex Functions

For nonstrongly convex \( F \), we can use a perturbation approach to establishing the convergence analysis here.

Suppose \( x^0 \) is the initial input and \( \mu_p \) is a positive parameter, adding a perturbation term \( \mu_p \|x - x^0\|^2 \) to Problem (1), we have:

\[
\min_{x \in \mathbb{R}^d} F(x) + \mu_p \|x - x^0\|^2 + \Omega(x).
\]

(61)

If we solve (61) with ADSGD, since we can treat \( F(x) + \mu_p \|x - x^0\|^2 \) as the data-fitting loss, we know the loss is \( \mu_p \)-strongly convex, we can obtain the convergence result for (61) as \( O(n + \frac{1}{\mu_p} s \log \rho (\frac{1}{e_j})) \).

Suppose \( \hat{x}_k \) be generated from the \( k \)-th iteration of the main loop in
Algorithm 2 where $k = O((n + \frac{L}{\mu_p})\log \frac{1}{\epsilon})$ and $\tilde{x}^*$ is the optimum solution of (61), let $|I| \geq \frac{L}{\mu}$ and $\eta < \frac{1}{4L}$, we obtain:

$$
E\mathcal{P}_k(\tilde{x}_k) + C_P - \mathcal{P}(\tilde{x}^*) - \mu_P \|\tilde{x}^* - x^0\|^2 \leq \frac{\epsilon}{2}.
$$

(62)

where $C_P$ is the expectation of the perturbation term, which is always positive. Thus, we have

$$
E\mathcal{P}_k(\tilde{x}_k) \leq \frac{\epsilon}{2} + \mathcal{P}(\tilde{x}^*) + \mu_P \|\tilde{x}^* - x^0\|^2 \leq \frac{\epsilon}{2} + \mathcal{P}(x^*) + \mu_P \|x^* - x^0\|^2
$$

(63)

where the second inequality is obtained because $\tilde{x}^*$ is the optimum solution of (61).

If we set $\mu_P = \frac{\epsilon}{2 \|x^* - x^0\|^2}$, we have

$$
E\mathcal{P}_k(\tilde{x}_k) - \mathcal{P}(x^*) \leq \epsilon.
$$

(64)

Since $2\|x^* - x^0\|^2$ is a constant, the overall complexity of Algorithm 1 for nonstrongly convex function is $k = O((n + \frac{L}{\epsilon})s \log \frac{1}{\epsilon})$, which also improves ProxSVRG and MRBCD with the overall complexity $O((n + \frac{L}{\epsilon})d \log \frac{1}{\epsilon})$ for nonstrongly convex function.

5 EXPERIMENTS

5.1 Experimental Setup

Design of Experiments: We perform extensive experiments on real-world datasets for two popular sparsity regularized models. Lasso shown as

$$
\min_{x \in \mathbb{R}^d} \frac{1}{n} \sum_{i=1}^{n} \frac{1}{2} (y_i - x^T_i x)^2 + \lambda \|x\|_1.
$$

(65)

and sparse logistic regression as

$$
\min_{x \in \mathbb{R}^d} \frac{1}{n} \sum_{i=1}^{n} (-y_i a^T_i x + \log(1 + \exp(a^T_i x))) + \lambda \|x\|_1.
$$

(66)

respectively to demonstrate the superiority of our ADSGD w.r.t. the efficiency.

To validate the efficiency of ADSGD, we compare the convergence results of ADSGD w.r.t. the running time with competitive algorithms ProxSVRG [30] and MRBCD [29, 33] under different setups. We do not include the results of ASGD because the naive implementation is very slow. The batch size of ADSGD is chosen as 10 and 20 respectively.

Datasets: Table 2 summarizes the benchmark datasets used in our experiments. Protein, Real-sim, Gisette, Mnist, and Rcv1.binary datasets are from the LIBSVM repository, which is available at...
### Table 2: The descriptions of the datasets.

| Dataset      | Samples | Features |
|--------------|---------|----------|
| PlantGO      | 978     | 3091     |
| Protein      | 17766   | 357      |
| Real-sim     | 72309   | 20958    |
| Gisette      | 6000    | 5000     |
| Mnist        | 60000   | 780      |
| Rcv1.binary  | 20242   | 47236    |

This is because, as the variables are discarded, the optimization process is mainly conducted on a sub-problem with a much smaller size and thus requires fewer inner loops. Meanwhile, the screening step imposes almost no additional costs on the algorithm. Thus, ADSGD can achieve a lower overall complexity, compared to MRBCD and ProxSVRG conducted on the full model.

5.2.2 Sparse Logistic Regression. Figures 3(a)-(c) provide the convergence results for sparse logistic regression on three datasets with $\lambda = \lambda_1$. The results also show that ADSGD spends much less running time than MRBCD and ProxSVRG for all the datasets, even when $n \gg d$ for Mnist dataset. This is because our method solves the models with a smaller size and the screening step imposes almost no additional costs for the algorithm.

6 CONCLUSION

In this paper, we proposed an accelerated doubly stochastic gradient descent for sparsity regularized minimization problem with linear predictors, which can save much useless computation by constantly identifying the inactive variables without any loss of accuracy. Theoretically, we proved that our ADSGD method can achieve lower overall computational complexity and linear rate of explicit model identification. Extensive experiments on six benchmark datasets for popular regularized models demonstrated the efficiency of our method.
