Abstract

Aim: The aim was to study the effect of supplementation of lysine producing microbes (LPM) as an in vivo source of lysine on performance and egg quality characters of post-peak layers.

Materials and Methods: BIS (1992) specified diets (except crude protein [CP] and lysine) were prepared using either soybean meal (SBM) or groundnut extractions (GNE) or sunflower extractions (SFE) with 16 and 15% CP resulting in six control diets. Further, each control diet was fortified with either synthetic lysine or LPM to meet BIS (1992) specified lysine requirement resulting in the set of 12 test diets. Each of the eighteen diets was offered to quadruplets groups of 4 post-peak (52 weeks) commercial laying hens in each. The trial lasted for 119 days.

Result: The results revealed that the feed consumption and body weight changes and Roche yolk color and yolk index were significantly (p ≤ 0.05) different among different treatments. However, egg production, feed efficiency, egg weight, egg shape index, Haugh unit score, albumen index and shell thickness, and net returns remained non-significant (p > 0.05) among different treatments. Among main factors, protein level (16% and 15% CP) made a significant (p ≤ 0.05) difference in egg production (79.6 and 75.1%) and feed efficiency (2.64 and 2.81 kg feed/kg egg mass, respectively). Among protein source GNE- and SFE-based diet fed groups showed significantly (p < 0.05) higher feed consumption and body weight gain than SBM based diets fed birds. Yolk color (7.0, 7.3 and 7.3, respectively) and yolk index (0.40, 0.38 and 0.43, respectively) were significantly (p ≤ 0.05) different from the protein sources. CP level and Protein source interaction effects showed significant differences in albumen index and Haugh unit score.

Conclusion: Optimum level of protein (16% CP) and GNE as a source of protein tended to be superior in increasing the performance and egg characteristics of post-peak layers and supplementation of lysine in either synthetic or LPM form found to be beneficial in optimizing their performance.

Keywords: egg characteristics, lysine, lysine producing microbes, post peak layers, performance.

Introduction

The profit in the poultry industry can be maximized by decreasing the feed cost which accounts 75% of the total cost of egg production. Several commercial guidelines for laying hens [1,2] were recommended for crude protein (CP) levels, which vary from 17.4% to 18.2% (19.1-20.0 g of CP/d) per hen. Which appeared to higher than the recommended range of many recent reports [3-6] higher levels of protein/amino acids in diet will increase nitrogen excretion, ammonia emission, and taxing the ecosystem by contaminating surface water bodies [7] also often result in higher feed cost. Blair et al.,[8] obtained optimum layer performance when they were fed on low-protein diet (13.5%), which was properly supplemented with essential amino acids compared to layers fed 17% CP diet. Several studies have been undertaken on alternatives that might reduce CP level and cost of feed supplements with better economic results [9].

Supplementation of the low protein diets with crystalline amino acid is becoming relevant in feed formulation to minimize the nitrogen excretion and cost of production [10]. Lysine being the second most essential amino acid in the diet of poultry playing important vital function in egg production in layers and cereals used in feed composition contain low level of lysine [11], hence it is normally supplemented in the diet in the form of synthetic lysine (a product of microbial fermentation). The supplementation of lysine in a
low protein diet has been found to increase egg mass, egg weight, and feed conversion in a sunflower seed cake based diet [8,12,13] reported that performance of layers fed control diet (16% CP) were comparable to those on the low-protein diet (14%) supplemented with essential amino acids. Supplementation of lysine may be in the form of synthetic lysine or any probiotic preparation, which can specifically synthesize adequate amount of lysine in the gut of the bird by utilizing the prevalent nitrogen. In addition to this, probiotics like Lactobacillus species [14] in layer diets did positively influence hen day egg production, feed conversion ratio (FCR), egg weight, and albumen quality, while decreasing serum cholesterol level. Dilworth and Day [15] reported that the supplementation of certain probiotics can specifically synthesize adequate amount of lysine in the gut of the bird by utilizing the prevalent nitrogen. Probiotics such as Lactobacillus species in layer diets did positively influence hen day egg production, feed efficiency, and egg weight [14].

Keeping in view the aforesaid facts, a comparative study was designed to put on record the effect of lysine producing microbes, a mixed culture of about ten microbes which can produce lysine in the gut of the birds compared with that of synthetic lysine in post-peak commercial layers using soya or ground-nut extraction or sunflower extraction protein source based diets at two levels of dietary protein.

Materials and Methods

Ethical approval

This research work was carried out as per the guidelines in force at the time of carrying out the experiment as well as in accordance with the International Ethics Committee guidelines to minimize pain or discomfort of the birds. The study was approved by the Institutional Ethics Committee.

Experimental design

A set of 18 experimental diets (Table-1) were formulated in a factorial design with two protein levels (16 and 15% CP), three protein sources (soybean meal [SBM], groundnut extractions [GNE], and sunflower extractions [SFE]) and with three lysine sources (no added lysine, synthetic lysine, and lysine producing microbes [LPM]). The LPM used in this study has been claimed to contain live lysine producing microbes, a mixed culture of about 10 microbes which can produce lysine in the gut of the birds compared with that of synthetic lysine in post-peak commercial layers using soya or ground-nut extraction or sunflower extraction protein source based diets at two levels of dietary protein.

Materials and Methods

Ethical approval

This research work was carried out as per the guidelines in force at the time of carrying out the experiment as well as in accordance with the International Ethics Committee guidelines to minimize pain or discomfort of the birds. The study was approved by the Institutional Ethics Committee.

Performance evaluation

The daily required quantity of specified diet was collectively offered to each replicate of four birds in divided dose of about 50% in morning and remaining 50% in the afternoon hours. All the birds were weighed individually at the beginning of the experiment as well as at every 28 days interval to monitor the pattern of body weight changes if any due to dietary regimen. The average body weight in the replicate group was then calculated. Egg produced from each replicate were recorded and weighed twice (Tuesday and Friday) in a week of the experimental period. The feed efficiency was calculated based on the amount of feed consumed to produce one kg egg mass as per replicate. On the terminal day of every 28-day interval, all the eggs produced from different replicate groups were collected and were weighed individually during the experimental period of 84 days. Further, on the immediate next day, each egg was broken and the entire contents were carefully placed on a glass slab for egg quality study. Albumen index score was calculated as the ratio height and diameter of thick albumen (in mm) which were measured by Ames® spherometer and by Vernier Caliper, respectively. Yolk index score, the ratio of height to diameter of yolk calculated in similar way. Egg shape index expressed as a relationship of length and breadth of the egg (in cm) obtained using Vernier Calipers. The height of albumin was recorded at two consistent places using Ames Haugh unit meter to obtain the Haugh unit score.

\[ \text{HUS} = 100 \log \left[ \frac{H - \sqrt{G} \left[ 30 (W^{0.37} - 100) + 10.57 \right]}{100} \right] \]

\( H \): is the height of albumen (mm)
\( G \): Gravitational force (981 cm/s; w weight of the egg)

The shell pieces devoid of shell membranes at a broad end, narrow end, and middle band were selected and their thickness was measured using a digital calipers. The average of all the three pieces was represented as shell thickness. The color of the yolk of every broken open egg was scored by matching (contrast) technique using Roche yolk color fan [17].

Statistical analysis

The data generated during the experiment were statistical analyzed by completely randomized design as well as by factorial design according to the methods described by Snedecor and Cochran [18].

Results

Production characteristics

The performance of layers under different treat ment is presented in Table-3. The average daily feed consumption ranged significantly (p ≤ 0.05) from 117.1 (16% CP, SBM, Syn. Lysine) to 127.5 g (15% CP, GNE, LPM). The cumulative average egg production varied from as low as 70.6 (15% CP, SBM, no lysine) to as high as 85.7% (16% CP, GNE, no lysine) however the differences were non-significant and no definitive trend was observed among different treatments. The feed efficiency, body weight gain, and net returns also remained non-significant among different treatments. Table-4 shows the influence of different main factors, 16 and 15% levels of protein showed significant (P ≤ 0.05) differences in egg production and feed efficiency. The egg production and feed efficiency was 79.6; 2.64 and 75.1; 2.82%, respectively, at 16 and 15% CP level in the diets. However, the

NS= Non-significant; * Means with different superscripts in a column differ significantly, LPM= Lysine producing microbes, SCM= Soya bean meal, SFE= Sunflower extractions, GNE= Groundnut extractions, CP= Crude protein

difference in feed consumption, body weight change, and net returns were non-significant (p > 0.05).

Among protein sources, the SCM based diet group of layers recorded significantly (p < 0.05) lower daily feed consumption (118.9 g) as against those of GNE (125.8 g) and SFE (124.1 g) groups. Weight gain was significantly higher in SFE (51.8) with lowest being SCM group (31.1). Egg production was 78.2 per cent in GNE groups while that of SCM (77.7%) and SFE (76.1%) groups which were statistically similar (p ≤ 0.05). Sources of lysine did not show any significant difference in production parameters. Various interaction effects (Table-4) viz., protein level × protein source, protein levels × supplemented lysine source and protein source × lysine source interaction also remained statistically non-significant (p > 0.05) in influencing the feed consumption, body weight gain, egg production, and net returns.

Egg quality characters

Level of protein, source of protein and lysine sources were non-significant in influencing egg weight, shape index, albumen index, Haugh unit
score and shell thickness (Table-5). However, the yolk color was significantly more in both GNE and SFE based diet and yolk index was highest in GNE based diets. Table-5 illustrate the interactions of the protein level x protein source, the SFE based 15% CP group has shown significantly (p ≤ 0.05) lower Haugh unit score (64.7) when compared to SFE based 16% group (68.1). Various treatments (Table-6), main factors and interaction effects showed non-significant (p > 0.05) influence on the average egg weight, egg shape index, albumen index, Haugh unit score, yolk color, egg shell thickness, and yolk index except CP level protein source interaction for albumen index, yolk index, and Haugh unit score.

Discussion

Production characteristics

Among different treatment, the feed consumption ranged significantly with, GNE-based diet fed group had highest feed consumption followed by that of SFE and SBM groups. Cumulative average egg production, feed efficiency, body weight gain, and net returns remained non-significant among different treatments. However, SFE-based groups showed numerically higher body weight gains (72 g) when compared to SBM based diet groups (17.4 g) which may be due to, relatively lower production (due to lower availability of lysine) in SFE group compared to soya groups leading to more body fat accumulation.

Level of protein in the diet significantly affected the egg production and feed efficiency this is in contrary to Chaiyapoom et al. [19] were he reported non-significant difference in production and feed intake at 15% and 16% level of protein and Ji et al. [20] also reported that egg production, daily egg mass, feed intake, and FCR were not affected in the low-protein groups. Contrarily, Bustany and Elwinger [21] and Parla et al.[22] reported lower feed intake in low protein diets with lysine levels ranging between 0.46 and 0.66%. Among the protein sources, the SBM based diet group of layers recorded significantly lower feed consumption, which was in contrary to Rose et al. [23] who in their study replaced lysine rich SBM diet with lysine deficit SFE diets which failed to show any significant difference in the performance of layers. Though GNE had higher lysine: Arginine antagonism [24], yet in the present study, a better egg production with GNE protein source appears to be due to better provision of lysine either from synthetic or LPM source [25]. The egg production, feed efficiency or net returns remained similar among groups fed SBM or GNE or SFE protein based diets in the present study. Regarding lysine source, no significant differences were observed in feed consumption, egg production, body weight, feed efficiency or net returns in birds fed control, synthetic lysine or LPM supplemented diets. Similar findings with supplemental lysine levels of 0.85, 0.98 and 1.18% in the diets of post-peak layers was observed by Vogt and Krieg [26] and Prochaska et al. [27]. Kurtoglu et al. [28], Panda et al. [29], and Bonekamp et al. [30] observed non-significant differences in performance of layers with supplementation of commercial probiotic preparation.

Control and LPM groups showed numerically higher feed consumption than synthetic lysine group. Such a trend is obvious since birds tend to consume more feed in the lysine deficiency [31] or the marginal deficiency of any specific amino acids [32] and in LPM supplemented group due to gut stabilization feed consumption in more [14]. Yalcin et al. [32] reported significant improvement (4.65%) in the egg production with a commercial probiotic preparation fed @ 0.75 kg/ton. Interactions of level of protein, sources of protein and lysine source did not show any significant difference. In contrary, Sherman et al. [25] and Parla et al. [22] noted better performance of birds fed low protein diets supplemented with lysine. In present study, SFE based protein with or without supplementation showed higher gain in body weight as compensatory to low egg production in these groups. Karunjeewa et al. [12] also reported higher gain in SFE group with lysine supplementation. The higher egg weights in GNE group were in effect due to higher feed consumption in GNE based group when compared to other groups and that the supplemented synthetic lysine has supported good egg weights. Bustany and Elwinger [21] and Sohail et al. [33] also reported numerical decrease in the feed efficiency in lysine deficit low protein group.

Egg characteristics

Numerically, the data indicated better shape index with supplementation of LPM in low protein groups. The main factors viz. protein level (16 and 15% CP), protein source (SBM, GNE, and SFE) and lysine source (no added lysine, synthetic lysine, and LPM) showed non-significant difference on egg weight, shape index, albumen index, Haugh unit score, and shell thickness this was also reported by Figueiredo et al. [34], who registered no individual effects of amino acids in the proportion of egg components.

Numerically, LPM supplementation was found to increase shape index, yolk color and yolk index. These results are similar to those of Sohail et al. [33] who reported non-significant increase in the shape index with supplementation of lysine. Balvi et al. [35] also reported similar results with supplementation of Protexin (commercial probiotic preparation). With regard to supplemented LPM, which showed statistical non-significance, the trend was similar to that of synthetic lysine [24,32]. Low protein group showed relatively higher shape index because of larger eggs in this group, this was in agreement with the results of Adeyemo et al. [36] findings. Shim et al. [37] also reported that egg quality characters were similar regardless of level of protein in the diet. The GNE based optimum protein group might be good enough to provide better digestible protein to support albumen index. With the protein level × lysine source combination also, the low protein group with no supplementation of lysine (0.054) had comparatively lower albumen index in relation to optimum protein with Synthetic lysine supplementation (0.058). Prochaska et al. [27] showed similar results with supplementation of lysine. With regards to the protein source × lysine source, the SBM based control group showed lower albumen index (0.052) when compared to GNE based control and synthetic lysine supplemented group’s (0.059). Various treatments and interaction remained non-significant in influencing Haugh unit score, similar findings were reported.
with commercial probiotic (Biocell) supplementation [32]. Optimum protein (16% CP) with synthetic lysine supplementation showed better score (67.5) when compared to non-supplemented optimum protein group (65.6) similar to the reports of Novak et al. [38] and Trindade et al. [39]. GNE-based synthetic lysine supplemented group showed better score (67.8) compared to SFE based non-supplemented group (65.1) and further that the influence of lysine supplementation did exert a positive influence. The dietary treatment with synthetic lysine has shown significant (p < 0.05) effect in improving the yolk color. The levels of protein showed non-significant difference, while protein sources, GNE and SFE significantly (p ≤ 0.05) increased the yolk color compared to SBM. Sohail et al. [33], also found marginal improvement in the yolk color but statistically it was non-significant. However, various interactions were tested statistically non-significant in influencing the yolk color. There was a significant (p < 0.05) variation in yolk index between different treatments. Among protein sources, birds fed SFE protein sourced diets showed significantly (p < 0.05) highest yolk index compared to GNE and SBM based diets fed groups. Supplementation of lysine in either forms was found to improve the yolk index, however, the differences were non-significant (p > 0.05). Among protein levels, low protein group (15% CP) showed higher index compared to optimum protein group (16% CP). It may be because of relatively lower production in low protein group leading to increased yolk size. Among the interaction effects, the SFE based low protein group showed significantly (p ≤ 0.05) higher yolk index (0.45) while GNE based optimum protein group was lowest (0.36). All the three levels of lysine in low protein group were of the same order in influencing the yolk index (0.42), but in optimum protein group with no supplementation it was the lowest index (0.36). Synthetic lysine supplemented SFE group showed higher index (0.44) compared to GNE based control and synthetic lysine groups (0.37). Various main factors and interactions showed statistical non-significance in influencing the average eggshell thickness. Among protein levels, optimum protein group showed better shell thickness compared to low protein group, which might have been due to an adequate supply of protein for shell matrix formation. SFE source protein showed thicker shell than GNE source because of lower egg production. LPM supplementation reduced the shell thickness.

It was concluded that the supplementation of lysine in the form of LPM was as good as synthetic lysine in optimizing the production performance of the birds; however, further studies are required in this direction to justify the above claim. Protein level was of greater significant in influencing the egg production and feed efficiency, indeed level of lysine to a some extent showed its importance but statistically it was not significant.

Authors’ Contributions

This study was part of MVSc research program of GUM. BSVR designed the research program as mentor and GUM conducted the research work. GG and TMP worked as co – mentors for the MVSc program, provided technical guidance and also helped in preparing this manuscript. NS and KSG helped in carrying out research trial, laboratory analysis and in manuscript preparation. All authors read and approved the final manuscript.

Acknowledgments

Authors are grateful to University of Agricultural Sciences, Bangalore, Karnataka, India for providing the funds for the study and also thankful to The Professor and Head, Department of Poultry Sciences, Veterinary College, Hebbal, Bangalore for providing necessary facilities for carrying out the research work presented in this paper.

Competing Interests

The authors declare that they have no competing interests.
