Two-dimensional transition metal dichalcogenides $MX_2$ ($M=W$, Mo, Nb, and $X=\text{Te, Se, S}$) with strong spin–orbit coupling possess plenty of novel physics including superconductivity. Due to the Ising spin–orbit coupling, monolayer NbSe$_2$ and gated MoS$_2$ of $2H$ structure can realize the Ising superconductivity, which manifests itself with in-plane upper critical field far exceeding Pauli paramagnetic limit. Surprisingly, we find that a few-layer $1T_d$ structure MoTe$_2$ also exhibits an in-plane upper critical field which goes beyond the Pauli paramagnetic limit. Importantly, the in-plane upper critical field shows an emergent two-fold symmetry which is different from the isotropic in-plane upper critical field in $2H$ transition metal dichalcogenides. We show that this is a result of an asymmetric spin–orbit coupling in $1T_d$ transition metal dichalcogenides. Our work provides transport evidence of a new type of asymmetric spin–orbit coupling in transition metal dichalcogenides which may give rise to novel superconducting and spin transport properties.
In conventional Bardeen–Cooper–Schrieffer (BCS) singlet superconductor, the external magnetic field becomes detrimental to the superconductivity state through orbital depairing effect and Pauli paramagnetism. In the two-dimensional (2D) atomically thin superconductor, the orbital effect is suppressed and Pauli paramagnetism plays the dominant role when an in-plane magnetic field is applied. The effect of in-plane magnetic field on the 2D superconductor is recently studied in the superconducting 2H-type transition metal dichalcogenides (TMDCs), including gated MoS$_2$, TaS$_2$, 2D NbSe$_2$, and monolayer TaS$_2$. Interestingly, the in-plane upper critical field $H_{c2,||}$ is observed to be strongly enhanced beyond the Pauli paramagnetic limit. The large enhancement of $H_{c2,||}$ in the 2H TMDCs originates from the strong Ising spin–orbit coupling (SOC) due to the breaking of an in-plane mirror symmetry and the presence of the out-of-plane mirror symmetry in the crystal structure. As electron spins are pinned to the out-of-plane directions, this phenomenon is named Ising superconductivity. Ising superconductivity with its promising applications in equal spin Andreev reflections, proximity phenomenon, engineering Majorana fermions, and topological superconductivity has sparked intense research interest in condensed matter physics. So far, the study of SOC effect on superconductivity in TMDCs is limited to the Ising SOC.

In this work, we systematically study the superconducting few-layer 1$T_d$-MoTe$_2$. A few-layer 1$T_d$-MoTe$_2$, unlike its 2H structure counterparts, breaks both the in-plane mirror symmetry and out-of-plane mirror symmetry. We show that the resulting SOC is asymmetric in the three spatial directions. By combining the low-temperature transport measurements and self-consistent mean-field calculations, we demonstrate that the in-plane upper critical field in the superconducting few-layer 1$T_d$-MoTe$_2$ exceeds the Pauli limit in the whole in-plane directions. Importantly, we theoretically predicted and experimentally verified that the in-plane upper critical field shows an emergent two-fold symmetry due to the new type of anisotropic SOC. From the experimental data, we further estimated that the SOC strength is on the orders of tens of meV, which is also consistent with the results of our first-principle calculations. Our work gives clear evidence that anisotropic SOC plays an important role in determining the properties of superconductivity in MoTe$_2$.

### Results

#### Growth of few-layer MoTe$_2$ crystals

In our experiment, the high crystalline few-layer MoTe$_2$ crystals were produced by molten-salt assisted chemical vapor deposition (CVD) method (see details in the Methods section and Supplementary Fig. 1). The optical images of the as-synthesized MoTe$_2$ layers with different thicknesses are shown in Fig. 1a. Similar to our previous results, the mono- and few-layer MoTe$_2$ can have a size up to 100 µm with a rectangular shape. Figure 1b shows the Raman spectra of the as-synthesized MoTe$_2$ with different layers, where we ascribe the Ag modes at 127, 161, and 267 cm$^{-1}$ to 1$T_d$-MoTe$_2$, which is further supported by the following scanning transmission electron microscopy (STEM) measurements. Note that the Ag mode located at 267 cm$^{-1}$ shows a blueshift with increasing sample thickness, which is similar to the Raman shift in other 2D materials such as MoS$_2$ and WS$_2$.

#### Structural characterization

The atomic structure of few-layer MoTe$_2$ is further characterized by annular dark-field (ADF) STEM imaging. Figure 1c shows the atom-resolved STEM image of few-layer MoTe$_2$ in a large scale (see Supplementary Fig. 2a, b for the chemical purity verified by energy-dispersive X-ray spectra). The 1$T_d$ phase and 1$T'$ phase share the same in-plane crystal structure (Supplementary Fig. 2c), but the two structures have different stacking. The 1$T'$ crystallizes in monoclinic shape and keeps the global inversion center, while the 1$T_d$ phase has the vertical stacking and belongs to the non-centrosymmetric space group $Pmm2_1$, as shown by the atomic models in Fig. 1c. Therefore, the projection of the scattering potential is different in these two phases and can be distinguished by their STEM images. At room temperature, bulk MoTe$_2$ usually crystallized in the monoclinic 1$T'$ phase. By comparing the simulated images both in 1$T_d$ and 1$T'$ phase shown in Fig. 1c, we unambiguously found that the few-layer MoTe$_2$ is in the 1$T_d$ phase rather than the bulk 1$T'$ phase at room temperature. This is different from the previous reports, where the 1$T_d$ phase only occurs at temperature below 200 K. Additionally, the temperature dependence of Raman spectra and sheet resistance shown in Supplementary Fig. 3 also confirm the 1$T_d$ phase in bulk MoTe$_2$, which is presumably caused by the reduced thickness of MoTe$_2$.

#### Transport properties of few-layer 1$T_d$-MoTe$_2$

Figure 1d shows the temperature dependence of the normalized four-terminal sheet resistance ($R_{\text{norm}}$), measured at zero magnetic field, for MoTe$_2$ films with thickness from 2 to 30 nm (see Supplementary Fig. 4 for raw data). At high temperatures, all samples showed a metallic behavior with $dR/dT > 0$, indicating that the phonon scattering dominates the transport. As the temperature is further lowered, the samples enter a disorder-limited transport regime prior to the eventual superconducting state. The residual resistance ratio, $R_{\text{RRR}} = R_{300K}/R_{60K}$, is reduced below 200 K. Additionally, the temperature dependence of Raman spectra and sheet resistance shown in Supplementary Fig. 3 also confirm the 1$T_d$ phase in bulk MoTe$_2$, which is presumably caused by the reduced thickness of MoTe$_2$.

At low temperatures, superconductivity is observed for all samples. To examine the thickness-dependent superconductivity, in the inset of Fig. 1d we show the temperature dependence of the reduced resistance, $r = R/R_{\text{norm}} = R/R_{300K}$, in a low-temperature regime ($T \leq 5.5$ K) for samples with different thickness. Empirically, critical transition temperatures for the superconductivity, $T_{c,\text{r}}$, can be extracted from the $R$ vs. $T$ curve. This is realized by picking up the points firstly encountered with the predefined reduced resistance $r$ from the normal state into the superconducting state. Such transition temperatures, extracted at typical values $r = 0.0, 0.5,$ and 0.9, are listed in Supplementary Table 1 for our samples with different thickness. It is found that, $T_{c,\text{r}}$ increase from 0.35 K to 3.16 K with increasing sample thickness from 2 nm to 30 nm, and the $T_{c,\text{r}}$ values of our samples are surprisingly higher than $T_{c,\text{r}} \approx 0.1$ K as reported in stoichiometric bulk MoTe$_2$. In bulk MoTe$_2$, Te-vacancy-enhanced superconductivity has been previously reported with the highest $T_{c,\text{r}} \sim 1.3$ K, which is still much lower than $T_{c,\text{r}} = 3.16$ K observed in our 30-nm-thick MoTe$_2$ crystals. In addition, a significant broadening on superconducting transition are observed for 2-nm-thick device, which can be attributed to the enhanced thermal fluctuations in two dimensions; similar behaviors have been observed in few-layer Mo$_x$C$_{23}$ and NbSe$_2$ superconductors reported recently.

The few-layer MoTe$_2$ crystals provide an ideal platform to study their transport properties in the 2D limit. To investigate the dimensionality of the superconductivity in few-layer MoTe$_2$, we firstly studied the temperature dependence of the upper critical magnetic field $\mu_0H_{c2}$, which is defined as the magnetic field corresponding to a predefined reduced resistance $r = R/R_{\text{norm}} = 0.5$. At lower temperatures, superconductivity is observed for all samples. To examine the thickness-dependent superconductivity, in the inset of Fig. 1d we show the temperature dependence of the reduced resistance, $r = R/R_{\text{norm}} = R/R_{300K}$, in a low-temperature regime ($T \leq 5.5$ K) for samples with different thickness. Empirically, critical transition temperatures for the superconductivity, $T_{c,\text{r}}$, can be extracted from the $R$ vs. $T$ curve. This is realized by picking up the points firstly encountered with the predefined reduced resistance $r$ from the normal state into the superconducting state. Such transition temperatures, extracted at typical values $r = 0.0, 0.5,$ and 0.9, are listed in Supplementary Table 1 for our samples with different thickness. It is found that, $T_{c,\text{r}}$ increase from 0.35 K to 3.16 K with increasing sample thickness from 2 nm to 30 nm, and the $T_{c,\text{r}}$ values of our samples are surprisingly higher than $T_{c,\text{r}} \approx 0.1$ K as reported in stoichiometric bulk MoTe$_2$. In bulk MoTe$_2$, Te-vacancy-enhanced superconductivity has been previously reported with the highest $T_{c,\text{r}} \sim 1.3$ K, which is still much lower than $T_{c,\text{r}} = 3.16$ K observed in our 30-nm-thick MoTe$_2$ crystals. In addition, a significant broadening on superconducting transition are observed for 2-nm-thick device, which can be attributed to the enhanced thermal fluctuations in two dimensions; similar behaviors have been observed in few-layer Mo$_x$C$_{23}$ and NbSe$_2$ superconductors reported recently.

The few-layer MoTe$_2$ crystals provide an ideal platform to study their transport properties in the 2D limit. To investigate the dimensionality of the superconductivity in few-layer MoTe$_2$, we firstly studied the temperature dependence of the upper critical magnetic field $\mu_0H_{c2}$, which is defined as the magnetic field corresponding to a predefined reduced resistance $r = R/R_{\text{norm}} = 0.5$.
Due to the high reactivity of oxygen and water vapor, few-layer, especially monolayer MoTe$_2$, samples deteriorate easily in ambient conditions. The following data were mainly collected on samples with the thickness ranging from 2.7 to 9 nm. 

Figure 2a, b shows the superconducting resistive transitions of a 8.6-nm-thick MoTe$_2$ device with the magnetic field perpendicular and parallel to the sample surface, respectively, measured at fixed temperatures. In both cases, one can see that the superconducting transition shifts gradually to lower magnetic fields with the increase of temperature. The temperature-dependent upper critical fields in directions parallel and perpendicular to the sample surface, denoted by $\mu_0 H_{c2 \perp}$ and $\mu_0 H_{c2 \parallel}$, respectively, are plotted in Fig. 2c. We found that the superconductivity was more susceptible to perpendicular magnetic fields than to parallel magnetic fields, and a large ratio of $H_{c2 \perp}/H_{c2 \parallel} \approx 7$ is obtained in the 8.6-nm-thick sample, indicating a strong magnetic anisotropy. This is true for all samples, and the ratio reaches up to 26 for 2.7-nm-thick sample (see Supplementary Fig. 5 for more samples). A linear temperature dependence was observed for $H_{c2 \perp}$, which can be well fitted by the phenomenological 2D Ginzburg–Landau (GL) theory,$^1$

$$H_{c2 \perp}(T) = \frac{\phi_0}{2\pi \xi_{GL}^2} \left( 1 - \frac{T}{T_{c0}} \right),$$

where $\xi_{GL}$ is the zero temperature GL in-plane coherence length and $\phi_0$ is the magnetic flux quantum, as shown by the blue dashed line in Fig. 2c that gives $\xi_{GL} = 20.79$ nm (see Supplementary Table 1 for more data on samples with different thickness). Compared with the sample thickness of 8.6 nm as measured by AFM (Supplementary Fig. 5f), the coherence length $\xi_{GL} = 20.79$ nm is approximately two times of the thickness, indicating that the depairing effect from the orbital magnetic field is strongly suppressed. As a result, the in-plane magnetic field-induced paramagnetism determines $H_{c2 \perp}(T)$.

The 2D behavior of the superconducting few-layer MoTe$_2$ is further confirmed by the experiments with tilted magnetic field. Figure 2d shows the magnetic field dependence of the sheet resistance $R$ under different $\theta$ at 0.3 K, where $\theta$ is the tilted angle between the normal of the sample plane and the direction of the applied magnetic field (the inset of Fig. 2e). Clearly, the superconducting transition shifts to higher field with the external magnetic field rotating from perpendicular $\theta = 90^\circ$ to parallel $\theta = 0^\circ$ (see Supplementary Fig. 6 for more data on different MoTe$_2$ samples). The upper critical field $\mu_0 H_{c2 \perp}$ was extracted from Fig. 2d and plotted in Fig. 2e as a function of the tilted angle $\theta$. In Fig. 2e, a cusp-like peak is clearly observed at $\theta = 90^\circ$, where the external magnetic field is aligned in parallel to the sample surface, which is apparently sharper for thinner sample (Supplementary Fig. 6). Curves fitted with the 2D Tinkham model$^4$ and 3D anisotropic GL model show the data consistency with both models for $\theta < 85^\circ$ and $\theta > 95^\circ$, whereas for $85^\circ < \theta < 95^\circ$, the cusp-shaped dependence can only be explained with the 2D Tinkham model as shown in Fig. 2f. It shows that our superconducting few-layer MoTe$_2$ manifests the 2D nature of the superconductivity. For a 2D superconductor with $d_{sc} \ll \xi_{GL}$, the $V-I$ dependence as a function of temperatures is measured and shown in Supplementary Fig. 6. The Berezinskii–Kosterlitz–Thouless
temperature is estimated to be \( T_{\text{BKT}} = 1.47 \) K, which is only slightly larger than \( T_{c,0} = 1.4 \) K of the sample. With the above evidences, the 2D superconductivity is convincingly confirmed in our few-layer 1T\(_d\)-MoTe\(_2\) samples.

**Discussion**

Now we turn to discuss the most important findings of our experiments, that is, the observation of the in-plane upper critical field \( (H_{c2,\parallel}) \) beyond the Pauli limit and the emergent two-fold symmetry of \( H_{c2,\parallel} \). In conventional BCS superconductors, sufficiently high external magnetic field can destroy the superconductivity by breaking Cooper pairs via the coexisting orbital\(^{1,25}\) and Zeeman spin splitting effect\(^{1,8}\). For the few-layer sample, the orbital effect of the in-plane magnetic field is greatly suppressed due to the reduced dimensionality\(^1\), and consequently \( H_{c2,\parallel} \) is solely determined by the interaction between the external magnetic field and the spin of the electrons. When the magnetization energy gained from the applied magnetic field approaches to the superconducting condensation energy, the Cooper pairs are broken and superconductivity is destroyed at the characteristic field given by the Clogston–Chandrasekhar\(^{1,8}\) or Pauli paramagnetic limit \( H_p = \sqrt{2\Delta_0/gh_\rho} \), where \( \Delta_0 = 1.76k_BT_c \) is the g factor, and \( h_\rho \) as the Bohr magneton. The observation of \( H_{c2,\parallel} \) in our few-layer MoTe\(_2\) is summarized in Fig. 3 for different samples. Figure 3a displays the superconducting transition in 1T\(_d\)-MoTe\(_2\) devices with various thicknesses under in-plane magnetic field measured at 0.3 K. Clearly, the superconductivity in 1T\(_d\)-MoTe\(_2\) can persist to higher in-plane magnetic field as the thickness is lowered down. From Fig. 3b, c, it can be seen that the values of \( H_{c2,\parallel} \) for the six typical samples with different thicknesses are all larger than \( H_p \) in marked contrast to their bulk counterpart that is well below the \( H_p \). More generally, the magnetic field dependence of the sheet resistance of a 3-nm-thick MoTe\(_2\) sample is further measured at \( T = 0.3 \) K (\( T = 0.07T_c \)) with different in-plane tilted angle \( \varphi \) as shown in Fig. 4a (see Supplementary Fig. 8 for \( T = 0.3T_c \), 0.6T\(_c\), and 0.95T\(_c\)). Surprisingly, an emergent two-fold symmetry of \( H_{c2,\parallel} \) has been observed in few-layer 1T\(_d\)-MoTe\(_2\) with the \( H_{c2,\parallel} \) beyond \( H_p \) in all the in-plane directions as shown in Fig. 4b. As the magnetic field tilted from x-axis (\( \varphi = 0^\circ \)) to y-axis (\( \varphi = 90^\circ \)) (the relation between the x- and y-axis and the crystal axis is shown in the Supplementary Fig. 9), we can see that the superconducting transition moves from higher field to lower field. From the low temperature (\( T = 0.07T_c \)) to the temperature near \( T_c \), the observed two-fold symmetry \( H_{c2,\parallel} \) stays robust. The phenomena were observed in another two samples with the thickness of 4.0 and 9.0 nm, respectively (Supplementary Figs. 10 and 11). Note that the observed \( H_{c2,\parallel} \) still stayed above the \( H_p \) while the in-plane anisotropy, \( H_{c2,0}^\perp/H_{c2,\parallel} \), decreased from 1.56 to 1.16 with the thickness increased from 4 to 9 nm. For thicker samples, as superconductivity is also influenced by orbital effects, it is reasonable that the anisotropy in \( H_{c2,\parallel} \) is reduced. The emergent two-fold symmetry observation in \( H_{c2,\parallel} \) which exceeds \( H_p \) at low
temperatures, is in sharp contrast with the standard BCS prediction and becomes highly nontrivial.

Similar anomalous enhancement of $H_{c2}$ has been observed in layered superconductors in the dirty limit with strong SOC, which can be explained by spin–orbit scattering (SOC) effect using the microscopic Klein–Luther–Beasley (KLB) theory. However, the isotropic SOS potential in the KLB theory can only result in the isotropic $H_{c2}$, which is inadequate to interpret our anisotropic $H_{c2}$ data. The anisotropic SOS potential is one possibility that can lead to the observed anisotropy, but it requires the impurities to have the SOS potentials with a common two-fold symmetry. This is unfeasible to realize in real materials. Moreover, the observed in-plane anisotropy is very robust and can be reproducible in many samples of different batches with different thickness, indicating that the effect is intrinsic rather than depending on some anisotropic disorder scattering. On the other hand, it is known that inhomogeneous superconducting states, such as Fulde–Ferrell–Larkin–Ovchinnikov (FFLO) state, or helical state, can also enhance $H_{c2}$, which have been observed in heavy Fermion superconductors, organic superconductors, and monolayer Pb films. However, for superconductors induced by FFLO state, the theoretical value of $H_{c2}$...
H_{2,||}/H_p is in the range of 1.5–2.5, smaller than the observed value of 2.8 in our 2.7-nm-thick sample. Moreover, the FFLO characteristic upturn\(^{12-14}\) of H_{2,||}(T_c) at low temperature is missing in our experimental data as shown in Fig. 3c. Therefore, the FFLO state can be ruled out.

Recently in monolayer NbSe\(_2\) and gated MoS\(_2\) superconductor, the anomalous enhancement of H_{2,||} beyond H_p has been interpreted by the Ising SOC protected Ising superconductivity mechanism\(^{23,24}\). A monolayer TMDCs with 2H structure possesses an out-of-plane mirror symmetry, whereas the in-plane inversion symmetry is broken. The mirror symmetry restricts the crystal field (\(\epsilon\)) to the plane, while the inversion symmetry breaking can induce strong SOC splitting, giving rise to an effective Zeeman-like magnetic field \(H_{zz}(k) \propto k \times \epsilon\) (~100 T for gated MoS\(_2\) and ~660 T for NbSe\(_2\)) with opposite out-of-plane direction at the K and –K valleys of the Brillouin zone\(^{40}\). Thus, the electron spins are pinned along the out-of-plane directions, and they are antiparallel to each other for electrons with opposite momenta; that is to say, spins of electrons of Cooper pairs are polarized by the large out-of-plane effective Zeeman field, and thus becomes insensitive to the external in-plane magnetic field, which results in the enhancement of in-plane H_{2,||}\(^{21}\). However, in few-layer MoTe\(_2\), the absence of out-of-plane mirror symmetry gives rise to a more complicated SOC field beyond the Ising SOC.

In order to fully understand the experimental results in the few-layer 1T\(_x\)-MoTe\(_2\), we focus on the 1T\(_x\)-MoTe\(_2\) bilayer and construct an effective model from the symmetry point of view. The crystal structure of bilayer 1T\(_x\)-MoTe\(_2\) is shown in Supplementary Fig. 9 and it has the same symmetry properties as bulk crystals where only the mirror symmetry in the y direction is preserved, while both the out-of-plane mirror symmetry and the in-plane mirror symmetry in the x direction are broken. Since the bilayer 1T\(_x\)-MoTe\(_2\) possesses the time reversal symmetry and the mirror symmetry in the y direction (Supplementary Fig. 9), the SOC at the Fermi level is restricted to an effective form \(H_{soc} = g \cdot \sigma\), with \(g = (x, \sin \varphi, y, \cos \varphi, z, \sin \varphi)\) in the first order approximation (the complete form is derived in the Supplementary Note 1), where \(\varphi\) is the polar angle for the Fermi wave vector. In the bilayer 1T\(_x\)-MoTe\(_2\), the breaking of in-plane mirror symmetry in the x direction generates the out-of-plane Ising component \(g_z\), and the breaking of the out-of-plane mirror symmetry gives rise to the anisotropic in-plane components (\(g_x, g_y\)) of the SOC. As a result, all the three components of SOC exist in the bilayer 1T\(_x\)-MoTe\(_2\). Similar to 2H structure TMDCs, \(g_z\) strongly enhances in-plane H_{2,||}\(^{21}\). Interestingly, the in-plane anisotropic SOC will give rise to a two-fold symmetry in in-plane H_{2,||} as discussed below.

To quantitatively validate the asymmetric SOC enhanced upper critical field, we calculate the in-plane spin susceptibility (see Supplementary Note 2 for the calculation procedure). At the zero temperature limit, the superconductor—normal metal transition driven by in-plane magnetic field occurs when \(\frac{1}{2} N_N H_{fi}^2 + \frac{1}{2} \chi_N H^2 = \chi_N H_{fi}^2\), where the two sides of the equation correspond to the energy for the superconducting state and the normal state, respectively. Here \(\chi_N\) and \(N_N\) denote the spin susceptibility of the superconducting state and the normal state, respectively, and \(N_p\) is the density of states at the Fermi level. In the presence of the SOC, the superconducting spin susceptibility has a finite value as is seen from Fig. 4c. The enhancement of the in-plane H_{2,||} by the SOC field becomes understandable since H_{2,||}(\varphi) = \sqrt{N_p/\chi_N} \Delta_o(\text{Supplementary Note 3}). The two-fold angle dependence of H_{2,||} is also consistently explained by the anisotropic in-plane spin susceptibility \(\chi_N\) shown in the inset of Fig. 4c.

In Fig. 4b, the in-plane H_{2,||}(\varphi) at zero temperature with two-fold symmetry is plotted with the SOC field at the Fermi level.

Methods

CVD synthesis of highly crystalline few-layer MoTe\(_2\). The few-layer MoTe\(_2\) samples were synthesized via CVD method inside a furnace with a 1-in. diameter quartz tube. Specifically, one alumina boat containing precursor powder (NaC\(_2\)MoO\(_4\) = 1:5) was put in the center of the tube. Si substrate with a 285-nm-thick Si\(_3\)N\(_4\) on top was placed on the alumina boat with polished side faced down. Another alumina boat containing Te powder was put on the upstream side of quartz tube at a temperature of about 450 °C. Mixed gas of H\(_2\)/Ar with a flow rate of 15/80 sccm was used as the carrier gas. The furnace was ramped to 700 °C at a rate of 50 °C/min and held there for about 4 min to allow the growth of few-layer MoTe\(_2\) crystals. After the reaction, the temperature was naturally cooled down to room temperature. All reagents were purchased from Alfa Aesar with purity exceeding 99%.

Raman characterization. Raman measurements with an excitation laser of 532 nm were performed using a WITec alpha 300R Confocal Raman system. Before the characterization, the system was calibrated with the Raman peak of Si at 520 cm\(^{-1}\). The laser power is <1 mW to avoid overheating of the samples.

TEM and STEM characterization. The STEM samples were prepared with a poly (methyl methacrylate) (PMMA)-assisted method. A layer of PMMA of about 1 µm thick was firstly spin coated on the wafer with MoTe\(_2\) samples deposited, and then baked at 180 °C for 3 min. The wafer was then immered in NaOH solution (1 M) overnight to etch the SiO\(_2\) layer. After lift-off, the PMMA/MoTe\(_2\) film was transferred into distilled (DI) water for several cycles to rinse off the residual contaminants, and then it was fished by a TEM grid (Quantifoil Au grid). The transferred specimen was dried naturally in ambient environment, and then dropped into acetone overnight to dissolve the PMMA coating layers. The STEM imaging on MoTe\(_2\) were performed on a JEOL 2100F with a cold field-emission gun and a DELTA aberration corrector operating at 60 kV. A Gatan GIF Quantum was used to record the EELS spectra. The inner and outer collection angles for the STEM images (p1 and p2) were 62 and 129–140 mrad, respectively, with a convergence semi-angle of 35 mrad. The beam current was about 15 pA for the ADF imaging and EELS chemical analyses. All imaging was performed at room temperature.

Devices fabrication and transport measurement. Few-layer MoTe\(_2\) samples were directly grown on SiO\(_2\)/Si substrate, which facilitate the device fabrication without the need for transferring the materials to an insulating substrate for transport measurement. After the growth of the sample, few-layer MoTe\(_2\)
crystals with the thickness ranging from 2 to 30 nm were firstly identified by their color contrast under optical microscopy. Then, small markers were fabricated using standard e-beam lithography near the identified sample for subsequent fabrication of Hall-bar devices. To obtain a clean interface between the electrodes and the sample, in situ argon plasma was employed to remove the resist residues before metal evaporation without breaking the vacuum. The Ti/Au (5/70 nm) electrodes were deposited using an electron-beam evaporator followed by lift-off in acetone. Transport experiments were carried out with a standard four-terminal method from room temperature to 0.3 K in a top-loading Helium-3 refrigerator with a 15 T superconducting magnet. A standard low-vapor pressure glove box was used to avoid deterioration once the device fabrication and transport measurement setup being completed. Water vapor, the few-layer MoTe2 samples should be stored in an Ar-filled glove box to avoid deterioration once the device fabrication and transport measurement setup being completed.

measurements and data analysis on STEM; W.-Y.H. and K.T.L. predicted the presence of the anisotropic SOC and its experimental implications. J.L. performed the first-principle calculations. G.L. prepared the manuscript with input from Z.L., J.L., J.Z., W.-Y.H., K.T.L., J.L., C.Y., and L.L. All the authors discussed the results and commented on the manuscript.
