Abstract

There has been growing interest in how economists can import machine learning tools designed for prediction to accelerate and automate the model selection process, while still retaining desirable inference properties for causal parameters. Focusing on partially linear models, we extend the Double ML framework to allow for (1) a number of treatments that may grow with the sample size and (2) the analysis of panel data under sequentially exogenous errors. Our low-dimensional treatment (LD) regime directly extends the work in [Chernozhukov et al., 2016], by showing that the coefficients from a second stage, ordinary least squares estimator attain root-n convergence and desired coverage even if the dimensionality of treatment is allowed to grow. In a high-dimensional sparse (HDS) regime, we show that second stage LASSO and debiased LASSO have asymptotic properties equivalent to oracle estimators with no upstream error. We argue that these advances make Double ML methods a desirable alternative for practitioners estimating short-term demand elasticities in non-contractual settings.

*We would like to thank Vasilis Syrgkanis, Whitney Newey, Anna Mikusheva, Brian Quistorff and participants of MIT Econometrics Lunch for valuable comments.
1 Introduction

Estimation of counterfactual outcomes is a key aspect of economic policy analysis and demands a large portion of the applied economist’s efforts in both industry and academia. In the absence of explicit exogenous variation – i.e., independence, randomization or experimentation – applied economists must rely on human judgment to specify a set of controls that allow them to assign causal interpretation to their estimates. This method of model selection is highly subjective and labor intensive. In response, there has been growing interest in the use of Machine Learning (ML) tools to automate and accelerate the economist’s model selection process [Athey, 2017]. The challenge here is to build estimators that can leverage ML prediction tools while still retaining desirable inference properties.

Recent work in econometrics and statistics has demonstrated the potential for use of ML methods in partialling out the influence of high-dimensional potential controls ([Belloni and Chernozhukov, 2013], [Belloni et al., 2016b]). In particular, the Double ML framework of [Chernozhukov et al., 2016] provides a general recipe for construction of control functions that can be used for inference on low dimensional treatment effects. In their partially linear model for cross-sectional data, Double ML requires first-stage estimation of both treatment and outcome functions of the high-dimensional controls. Using sample splitting, the out-of-sample residuals from these models represent exogenous variation that can be used to identify a valid causal effect in a second stage regression.

We argue that adaptations and extensions of this approach will be useful in a variety of common applied econometric problems. In this paper, we focus on extensions that will enable application to firm-side demand analysis. In such settings, the econometrician works with panel data on the prices and sales of their firm’s products. They will typically have available very rich item descriptions – product hierarchy information, textual descriptions, reviews, and even product images. Being on the firm side, they will also have access to the universe of demand-side variables that were used in strategic price-setting. Thus, they can confidently identify price sensitivities by assuming that after conditioning on the available demand signals, the remaining variation in price is exogenous. Moreover, the novel algorithms proposed in this paper will allow us to use the rich item descriptions to index heterogeneous product-specific price sensitivities.

Unlike most existing demand analysis frameworks, we do not require the presence of instrumental variables (e.g. cost or mark-up shifters) to identify demand elasticities. Instead, we assume that our possession of the universe of demand signals known to the firm
allows us to project out the systematic component of a firm’s pricing rule and ‘discover’
events of exogenous price variation. Of course, such an assumption may not always be
realistic for economists that do not work at, or with, the firms of interest. But, given
this information, the Double ML framework facilitates valid identification by allowing us
to learn the control functions defined on these high-dimensional demand signals without
over-fitting. Moreover, this approach allows us to use all residual price variation to learn
price sensitives. We thus are likely to achieve much more precise estimation than BLP
type approaches who derive identification from a small number of cost shifters. This
precision will be of primary importance to an industrial practitioner looking optimize
future price and promotion decisions. Finally, BLP models may often derive identifi-
cation from markup shifters (e.g. sums of characteristics of competing products) that
impact a firm’s chosen price. However, these markup shifters (often referred to as “BLP
instruments”) are typically combined with an assumption of Bertrand-Nash rationality
in order to generate valid moment conditions and thus are of limited utility for a firm
assessing the optimality of it’s own pricing decisions.

The proposed Double ML framework for estimating demand elasticities is as follows.
First, we estimate reduced form relations of expected log price and sales conditional
on all past realizations of demand system (lagged prices and sales). This is purely
a prediction problem and we seek to maximize out of sample fit. Any additionally
available demand signals should also be used subject to the constraint of not using any
“bad controls” that might be impacted by the realized price decision. The residuals
from our price model (“price surprises”) may then be interacted with product, location,
or channel characteristics in order to produce a vector of treatments which can then
be regressed against our sales residuals in a second stage estimation. The resulting
coefficients then correspond to heterogeneous demand elasticities. Often, a researcher
may want to select a sparse model from a high-dimensional set of possible heterogeneous
effects. For such cases, we provide appropriate results on the use of Lasso as a second
stage estimator, or when inference is desired, we suggest a debiased Lasso (similar to
[Javanmard and Montanari, 2014]) to construct point-wise and simultaneous confidence
intervals for the estimates of elasticities.

There are several methodological innovations necessary to extend from the original
Double ML work to this real-world demand analysis scenario. The first concerns the large

---

1 As an example, contemporaneous search volumes could be impacted by the choice to put a product
on discount and thus should be excluded from our first stage models.
2 One such case may be when products are classified in a hierarchical structure and we may assume
that the majority of product types in a particular node of the hierarchy have similar demand elasticities.
Demand elasticities, modeled via such hierarchy, may have a sparse representation.
number of goods (and therefore treatment effects) in our setting. \cite{Chernozhukov2016} shows the validity of Double ML only for the application of a second stage OLS estimator to an asymptotically fixed number of treatments. Our first contribution is to show that such estimates yield valid inference even if the dimensionality of treatment is allowed to grow. If our first-stage estimates have rate $o(N^{-1/4-\delta})$ for some $\delta > 0$, then we may accommodate a dimension of treatment that grows at rate $d = o(N^{4\delta/3})$. This result is presented in our Low Dimensional regime Section 3.2. Relaxing this requirement still further, we consider a High Dimensional Sparse framework, where we replace second-stage OLS used in original Double ML by Lasso for estimation and a version of debiased Lasso for inference. We show that the Lasso penalty is compatible with the noise incurred in our first-stage. In particular, Lasso achieves the oracle rate and debiased Lasso achieves the oracle asymptotic distribution. Moreover, the latter can be used to test large number of hypotheses (which may be necessary for inference on elasticities composed from coefficients on many heterogeneous treatments).

Another innovation of our method is the panel setting with item heterogeneity. We adopt correlated random effects approach and model item heterogeneity using dynamic panel Lasso \cite{Kock2016}, allowing for weakly sparse unobserved heterogeneity. Given the richness of our item descriptions, we find this to be a plausible assumption. In case one is willing to make a stronger assumption of zero unobserved heterogeneity, any ML algorithm can be used at the first stage.

Finally, we extend the original Double ML framework to allow for affine modifications of a single residualized treatment variable. Applying Double ML to a high-dimensional vector of treatments would typically require a separate residualization operation for each treatment. However, in demand applications, all treatments will often be affine modifications of price. For example, interaction of price with time-invariant observables corresponds to heterogeneous own-price elasticities and leave-me-out averages may model average cross-price effects within a product category. Example 2 gives more details about such examples. As a result of affine construction, we need only train a first-stage estimator for a single price variable, instead of each affine treatment separately. This achieves better precision of the first-stage estimates and speeds up computational time.

We then apply our new estimators to the problem of learning price sensitivities for a major food distributor. We posit a high-dimensional, log-linear demand model in which a products’ sales may be impacted by a large number of treatments that allow for a rich pattern of heterogeneous own and cross-price elasticities. We assume that after conditioning on available demand signals, remaining variation in price is exogenous and can be used for identification of price sensitivities. Usage of ML technique and
access to all of demand-side variables observed by business decision makers validates our identification. Finally, the distributor agreed to randomize prices across different location, which provides external validity for our results.

The rest of the paper proceeds as follows. Section 2 describes our partially linear framework and gives some motivating examples. Sections 3 provide our main theoretical results for the Low Dimensional and High Dimensional Sparse regimes. Section 4 discusses strategies and results for first stage estimation of treatment and outcome. Section 5 presents the empirical results from our work with the food distributor.

2 Econometric Model and Motivating Examples

2.1 Motivating Examples

Our paper provides a framework for analyzing a rich variety of examples, some of which we illustrate below.

Example 1 (Heterogeneous Treatment Effects with Modeled Heterogeneity).

Consider the following measurement model for treatment effects:

\[ Y_{it} = D_{it}' \beta_0 + g_{i0}(Z_{it}) + U_{it}, \quad \mathbb{E}[U_{it}|D_{it}, Z_{it}, \Phi_t] = 0 \]  
\[ D_{it} = P_{it}X_{it} \]  
\[ P_{it} = p_{i0}(Z_{it}) + V_{it}, \quad \mathbb{E}[V_{it}|Z_{it}, \Phi_t] = 0 \]

where \( Y_{it} \) is a scalar outcome of unit \( i \) at time \( t \), \( P_{it} \) is a “base” treatment variable, \( X_{it} = (1, \tilde{X}_{it}) : \mathbb{E}\tilde{X}_{it} = 0 \) is a \( d \)-vector of observable characteristics of unit \( i \), and \( Z_{it} \) is a \( p \)-vector of controls, which includes \( X_{it} \). The technical treatment vector \( D_{it} \) is formed by interacting the base treatment \( P_{it} \) with covariates \( X_{it} \), creating a vector of high-dimensional treatments. The set \( \Phi_t = \{Y_{i,k}, P_{i,k}, Z_{i,k}\}_{k=1}^{t-1} \) denotes the full information set available prior to period \( t \). In practice we will assume that this set is well approximated by the several lags of outcome and base treatment variables. Equation (2.3) keeps track of confounding, that is, the effect of \( Z_{it} \) on \( P_{it} \). The controls \( Z_{it} \) affect the treatment \( P_{it} \) through \( p_{i0}(Z_{it}) \) and the outcome through \( g_{i0}(Z_{it}) \).

In order to enable a causal interpretation for the parameters in the first measurement equation, we assume the conventional assumption of conditional sequential exogeneity holds, namely that the stochastic shock \( U_{it} \) governing the potential outcomes is mean independent of the past information \( \Phi_t \), controls \( Z_{it} \) and contemporaneous treatment variables \( P_{it} \) (and hence the technical treatment.) Equation (2.1) is the main measure-
ment equation, and
\[ \beta_0 = (\alpha_0, \gamma_0') \]
is the high-dimensional parameter of interest, whose components characterize the treatment effect via
\[ \Delta D_{it}' \beta_0 = \Delta P_{it} X_{it}' \beta_0 = \underbrace{\alpha_0}_{\text{ATE}} + \underbrace{X_{it}' \beta_0}_{\text{TME}}, \]
where \( \Delta \) denotes either a partial unit difference or a partial derivate with respect to the base treatment \( P_{it} \). We see that
- \( \alpha_0 \) is the Average Treatment/Structural Effect (ATE), and
- \( X_{it}' \beta_0 \) describes the so-called Treatment/Structural Modification Effect (TME).

It is useful to write the equations in the “partialled out” or “residualized” form:
\[ \tilde{Y}_{it} = \tilde{D}_{it}' \beta_0 + U_{it} = \tilde{P}_{it} X_{it}' \beta_0 + U_{it} \quad (2.4) \]
where
\[ \tilde{P}_{it} = P_{it} - \mathbb{E}[P_{it} | Z_{it}, \Phi_t] \]
and
\[ \tilde{Y}_{it} = Y_{it} - \mathbb{E}[Y_{it} | Z_{it}, \Phi_t] \]
denote the partialled out treatment and outcome, respectively. We assume that after conditioning on \( Z_{it} \),
\[ \{ (\tilde{P}_{it}, \tilde{Y}_{it})^T \}_{i=1}^T \]
is an i.i.d sequence across \( i \). For each \( i \), \( \{ \tilde{P}_{it}, \tilde{Y}_{it} \}_{t=1}^T \) is a martingale difference sequence by time.

A key insight of our orthogonal/debiased machine learning is that we will be able to construct high quality point estimators and confidence parameters for both \( \alpha_0 \) and the high-dimensional parameter \( \gamma_0 \), by essentially first estimating the residualized form of the equations above and then performing either ordinary least squared or lasso with de-biasing on the residualized form given above\(^3\).

---

\(^3\)This partialling out approach has classical roots in econometrics, going back at least to Frisch and Waugh. In conjunction with machine learning, it was used in high-dimensional sparse linear models in [Belloni et al., 2014] and with generic machine learning methods in [Chernozhukov et al., 2016]; in the latter paper only low-dimensional \( \beta_0 \)'s are considered, and in the former high-dimensional \( \beta_0 \)'s were considered.
Example 2 (Demand Functions with Cross-Price Effects). Consider the following model:

\[ Y_{it} = D_{it}' \beta_0 + g_{i0}(Z_{it}) + U_{it}, \quad \mathbb{E}[U_{it}|D_{it}, Z_{it}, \Phi_t] = 0 \quad (2.5) \]

\[ D_{it} = [P_{it}X_{it}, P_{-it}X_{it}] \quad (2.6) \]

\[ P_{it} = p_{i0}(Z_{it}) + V_{it}, \quad \mathbb{E}[V_{it}|Z_{it}, \Phi_t] = 0 \quad (2.7) \]

where \( Y_{it} \) is log sales of product \( i \) at time \( t \), \( P_{it} \) is a log price, \( X_{it} = (1, X_{it}) \) is a \( d \)-vector of observable characteristics, and \( Z_{it} \) is a \( p \)-vector of controls, which includes \( X_{it} \). Let \( C_i \) be a set of products which have a non-zero cross-price effect on sales \( Y_{it} \). For a product \( i \), define the average leave-\( i \)-out price of products in \( C_i \) as:

\[ P_{-it} = \frac{\sum_{j \in C_i} P_{it}}{|C_i|} \]

The technical treatment \( D_{it} \) is formed by interacting \( P_{it} \) and \( P_{-it} \) with observable product characteristics \( X_{it} \), creating a vector of heterogeneous own and cross price effects. The \( \Phi_t = \{Y_{ik}, P_{ik}, Z_{ik}\}^{t-1}_{k=1} \) denotes the full information set available prior to period \( t \), spanned by lagged realizations of demand system. In practice we will assume that this set is well approximated by the several lags of own sales and price. Equation (2.7) keeps track of confounding, that is, the effect of \( Z_{it} \) on \( P_{it} \). The controls \( Z_{it} \) affect the price variable \( P_{it} \) through \( p_{i0}(Z_{it}) \) and the sales through \( g_{i0}(Z_{it}) \). Conditional on observables, the sales shock \( U_{it} \) is mean independent of the past information \( \Phi_t \), controls \( Z_{it} \), price \( P_{it} \) and \( P_{-it} \).

Equation (2.5) defines the price effect of interest

\[ \beta_0 = (\beta_0^{own}, \beta_0^{cross}) \]

where \( \beta_0^{own} \) and \( \beta_0^{cross} \) are \( d/2 \) dimensional vectors of own and cross-price effect, respectively. The change in own price \( \Delta P_{it} \) affects the demand via

\[ \Delta D_{it}' \beta_0 = \Delta P_{it}X_{it}\beta_0^{own} \]

and the change in an average price \( \Delta P_{-it} \) affects the demand via

\[ \Delta D_{it}' \beta_0 = \Delta P_{-it}X_{it}\beta_0^{cross} \]

Let

\[ \beta_0^{own} = (\alpha_0^{own}, \gamma_0^{own}) \quad \text{and} \quad \beta_0^{cross} = (\alpha_0^{cross}, \gamma_0^{cross}) \]
We see that

- $\alpha_0^{\text{own}}$ is the Average Own Elasticity and $X_{it}'\gamma_0^{\text{own}}$ is the Heterogenous Own Elasticity
- $\alpha_0^{\text{cross}}$ is the Average Cross-Price Elasticity and $X_{it}'\gamma_0^{\text{cross}}$ is Heterogenous Cross-Price Elasticity

It is useful to write the equations in the “partiallyled out” or “residualized” form:

\[ \tilde{Y}_{it} = \tilde{D}_{it}'\beta_0 + U_{it} = [\tilde{P}_{it}'X_{it}', \tilde{P}_{it}^{-}X_{it}']\beta_0 + U_{it} \]  
(2.8)

where

\[ \tilde{P}_{it} = P_{it} - \mathbb{E}[P_{it} \mid Z_{it}, \Phi_t] \]
\[ \tilde{Y}_{it} = Y_{it} - \mathbb{E}[Y_{it} \mid Z_{it}, \Phi_t] \]

denote the partiallyled out log price and sales, respectively.

Note that the definition of $P_{-i,t}$ implies the very strong restriction that any two products $j$ and $k$ have the same cross-price impact onto a third product $i$. This is certainly an unrealistic depiction of cross-price effects. If (for example) we believed that our products engaged in logit competition we might prefer to construct $P_{-i,t} \equiv \sum_{j \neq i} \omega_j \cdot P_{j,t}$, with $\omega_j$ proportional to the popularity of product $j$. However, our high-dimensional framework enables us to consider many possible definitions of cross-price elasticities effectively horse-racing different theories of competition. By contrast structural models of demand rarely offer models of substitution at all different from that implied by a simple logit demand model [Gandhi and Houde, 2016].

Example 2 illustrates the orthogonal machine learning framework for firm-side demand analysis. Specifically, we view our reduced form equations as a best linear approximation to a true demand model in a short run, that business practitioners can use to forecast the impact of planned price changes. The controls $Z_{it}$ contain product information, lagged realizations of market quantities, and demand-side variables used for strategic price setting. Conditional on the pre-determined information in $Z_{it}$, the residual price variation $\tilde{P}_{it}$, can be credibly used to identify own and cross price effects. A high-dimensional vector $X_{it}$ summarizes rich product descriptions, time, and demographic information. Using the methods of this paper we are able to deliver high-quality point estimates and confidence intervals for both average effects $\alpha_0^{\text{own}}$ and $\alpha_0^{\text{cross}}$ and high-dimensional heterogeneous effects $\gamma_0^{\text{own}}$ and $\gamma_0^{\text{cross}}$ by first estimating the residualized form of the equations above and then performing either ordinary least squared or lasso with de-biasing on the residualized form given above.
2.2 The Econometric Model

Throughout our analysis, we consider a sequentially exogenous, partially linear panel model
\[ Y_{it} = D_{it}' \beta_0 + g_{i0}(Z_{it}) + U_{it} \quad \mathbb{E}[U_{it}|D_{it}, Z_{it}, \Phi_t] = 0, \tag{2.9} \]
\[ D_{it} = d_{i0}(Z_{it}) + V_{it} \quad \mathbb{E}[V_{it}|Z_{it}, \Phi_t] = 0 \tag{2.10} \]

where the indices \( i \) and \( t \) denote an item \( i \in [I] \equiv \{1, 2, \ldots, I\} \) and a time period \( t \in [T] \equiv \{1, 2, \ldots, T\} \), respectively. The variables \( Y_{it}, D_{it} \) and \( Z_{it} \) denote a scalar outcome, \( d \)-vector of treatments, and \( p \)-vector of controls respectively. The set \( \Phi_t = \{Y_{i,k}, P_{i,k}, Z_{i,k}\}_{k=1}^{t-1} \) denotes the full information set available prior to period \( t \). In practice we will assume that this set is well approximated by the several lags of outcome and treatment variables.

Let the set of items \( I \) belong to \( M \) independent groups of size \( C \)\footnote{The choice of the different group size \( C_g \approx C \) fits our framework.}:
\[ [I] = \{(m,c), m \in \{1, 2, \ldots, M\}, c \in \{1, 2, \ldots, C\}\} \]

denote by \( m(i) \) the index of the group of item \( i = (m,c) \). When making asymptotic statements in Section 3 we assume that cluster size \( C \) is fixed and the total sample size \( N = MCT \rightarrow \infty, d = d(N), p = p(N) \rightarrow \infty \) unless restricted otherwise. The parameter \( \beta_0 \) is our object of interest. We consider two regimes for \( \beta_0 \): a low-dimensional (LD) regime with \( d = O(N/\log N) \) and a high-dimensional sparse (HDS) regime \( d = d(N) > N, \|\beta_0\|_0 = s_N = o(\sqrt{N/\log p}) \).

Now define the \emph{reduced form objects}
\[ l_{i0}(z) \equiv \mathbb{E}[Y_{it}|Z_{it} = z, \Phi_t] = \mathbb{E}[Y_{it}|Z_{it} = z] \tag{2.11} \]
\[ d_{i0}(z) \equiv \mathbb{E}[D_{it}|Z_{it} = z, \Phi_t] = \mathbb{E}[D_{it}|Z_{it} = z] \]

and the corresponding residuals
\[ \bar{D}_{it} \equiv D_{it} - d_{i0}(Z_{it}) \tag{2.12} \]
\[ \bar{Y}_{it} \equiv Y_{it} - l_{i0}(Z_{it}). \]

We will also use the notation \( \bar{D}_{m,t} = [\bar{D}_{1,t}, \ldots, \bar{D}_{c,t}]' \) to denote a \( C \times d \) dimensional matrix of residuals and \( U_{m,t} = [U_{1,t}, \ldots, U_{c,t}]' \) be a \( C \times 1 \) dimensional vector of disturbances, corresponding to the cluster \( g \in G \).
Equation (2.9) implies a linear relationship between outcome and treatment residuals:

\[ \tilde{Y}_{it} = \tilde{D}_{it} \beta_0 + U_{it}, \quad \mathbb{E}[U_{it} | \tilde{D}_{it}] = 0. \]  

The structure of all the estimators is as follows. First, we construct an estimate of the first stage reduced form \( \tilde{d}, \tilde{l} \) and estimate the residuals:

\[ \tilde{D}_{i,t} = D_{i,t} - \tilde{d}(Z_{i,t}) \quad \tilde{Y}_{i,t} = Y_{i,t} - \tilde{l}(Z_{i,t}) \]

Second, we apply off-the-shelf LD (least squares) and HDS (Lasso, and debiased Lasso) methods, designed for linear models with exactly measures regressors and outcome. Since the true values of the residuals \( \tilde{P}_it \) and \( \tilde{Y}_{it} \) are unknown, we plug in estimated residuals that are contaminated by the first-stage approximation error. Under high-level conditions on the first stage estimators, we show that the modified estimators are asymptotically equivalent to their infeasible (oracle) analogs, where the oracle knows the true value of the residual. These high-level conditions are non-primitive and require verification for panel data. However, if the observable unit descriptions are sufficiently rich to assume weak sparsity of unobserved heterogeneity as in Example 3, these conditions hold for dynamic panel Lasso estimator of [Kock and Tang, 2016].

**Example 3** (Weakly Sparse Unobserved Heterogeneity). Consider the setup of Examples 1 and 2. Assume that

\[ g_{i0}(Z_{it}) = g_{0}(Z_{it}) + \xi_i \]
\[ d_{i0}(Z_{it}) = d_{0}(Z_{it}) + \eta_i \]

where \( g_{0}(\cdot) \) and \( d_{0}(\cdot) \) are weighted averages of item-specific functions \( g_{i0}(\cdot), d_{i0}(\cdot) \), and \( \eta_i, \xi_i \) is the time-invariant heterogeneity of item \( i \) in outcome and treatment equations. Ignoring \( \xi_i, \eta_i \) creates heterogeneity bias in the estimate of treatment effect. To eliminate the bias, we project \( \xi_i, \eta_i \) on space of time-invariant observables \( \bar{Z}_i \):

\[ \lambda_0(\bar{Z}_i) \equiv \mathbb{E}[\xi_i | \bar{Z}_i] \quad \text{and} \quad \gamma_0(\bar{Z}_i) \equiv \mathbb{E}[\eta_i | \bar{Z}_i] \]

We assume that \( \bar{Z}_i \) contains sufficiently rich item descriptions such that \( a_i \equiv \xi_i - \lambda_0(\bar{Z}_i) \) and \( b_i = \eta_i - \gamma_0(\bar{Z}_i) \) are small. We impose weak sparsity assumption: (see,
Under this assumption, the parameters to be estimated are the functions $g_0, \lambda_0, d_0, \gamma_0$ and the vectors $a = (a_1,..,a_N)'$ and $b = (b_1,..,b_N)'$. Section 4 describes an example of an $l_1$-penalized method by [Kock and Tang, 2016] that estimates these parameters with sufficient quality under sparsity assumption on $g_0, \lambda_0, d_0, \gamma_0$.

2.3 The Panel Double ML Recipe

All the methods considered in this paper will involve some variation on the Panel Double ML Recipe outlined below.

**Definition 2.1 (Panel Double ML Recipe).** 1. Split the data into a $K$-fold partition by time index with the indices included in each partition $k$ are given by:

$$I_k = \{(i,t) : \lfloor T(k-1)/K \rfloor + 1 \leq t \leq \lfloor Tk/K \rfloor \}.$$  

2. For each partition $k$, use a first stage estimator to estimate reduced form objects $\hat{d}_k, \hat{l}_k$ by excluding the data from partition $k$ (using only $I_k^c$).

3. Compute first stage residuals according to (2.12). For each data point $i$, use the first stage estimators who’s index corresponds to their partition.

4. Pool the first stage residuals from all partitions and Estimate $\hat{\beta}$ by applying a second stage estimator from Section 3.2 or 3.3 depending on its regime of $\beta_0$.

The recipe above outlines our sample splitting strategy. Step (1) partitions the data into $K$ folds by time indices. Steps 2 and 3 describe a cross-fitting procedure that ensures that the fitted value of the treatment $\hat{d}_{it} = \hat{d}_i(Z_{it})$ and outcome $\hat{l}_{it} = \hat{l}_i(Z_{it})$ is uncorrelated with the true residuals $\tilde{D}_{it}, \tilde{Y}_{it}$. Step (4) specifies our second stage estimation strategy. In the LD regime, we use ordinary least squares as our second stage estimator. In the HDS regime, we instead suggest Lasso for estimation and debiased
Lasso for inference.

3 Theoretical Results

In this section, we establish the asymptotic theory of our estimators under high-level conditions, whose plausibility we discuss in Section 4. We shall use empirical process notation, adapted to panel clustered setting.

\[ E_N f(x_{it}) \equiv \frac{1}{N} \sum_{(i,t)} f(x_{it}) \]

and

\[ G_N f(x_{it}) \equiv \frac{1}{\sqrt{N}} \sum_{(i,t)} (f(x_{it}) - E f(x_{it})) \]

3.1 High-Level Assumptions

In this section, we provide high-level restrictions of our estimators. They consist of assumptions on performance of the first-stage estimators (Assumption 3.1 and 3.2), standard identifiability (3.4), and light tails conditions on the true outcome and treatment residuals \( \tilde{Y}, \tilde{D} \) (3.5). In addition to that, we also assume Law of Large Numbers for matrices that are sample average of a stationary process (3.3).

First we must suppose that our first stage estimators \((\hat{d}, \hat{g})\) belong with high probability to the realization sets \( D_N \) and \( L_N \), respectively. Each of which are properly shrinking neighborhoods of \( d_0(\cdot), l_0(\cdot) \). We constrain these sets by the following assumptions.

**Assumption 3.1 (Small Bias Condition).** Define the following rates:

\[ m_N \equiv \sup_{d \in D_N} \max_{1 \leq j \leq d} \left( \frac{E(d_j(Z) - d_{0,j}(Z))^2}{2} \right)^{1/2} \]

\[ l_N \equiv \sup_{l \in L_N} \left( \frac{E(l(Z) - l_0(Z))^2}{2} \right)^{1/2} \]

\[ \exists D, L \sup_{d \in D_N} \max_{1 \leq j \leq d} |d_j(Z_{it})| < D \sup_{l \in L_N} |l(Z_{it})| < L. \]

\(^5\)This cross-fitting procedure corresponds to DML2 estimator of [Chernozhukov et al., 2016]. A more popular alternative, known as DML1, requires computation of a separate estimator of \( \beta \) on each partition \( k \) and returns the average over \( K \) final estimators. But Remark 3.1 of [Chernozhukov et al., 2016], shows that DML2 has a finite sample advantage over DML1. In addition it is more computationally efficient for large data sets. For this reason, all code and analysis in this project will use DML2, but similar results could be obtained for DML1 or other similar sample splitting and cross-fitting patterns.

\(^6\)The goal of partition by time is to ensure that every fold contains sufficient number of observations for each item \( i \). Alternative splitting procedures that output balanced partitions are also acceptable.
We assume that there exists $0 < \delta < \frac{1}{2}$:

$$l_N = o(N^{-1/4-\delta}), \quad m_N = o(N^{-1/4-\delta}).$$

We shall refer to $m_N$ as treatment rate and to $l_N$ as the outcome rate, and to $\delta$ as quality parameter.

**Assumption 3.2** (Concentration). *Let the centered out-of-sample mean squared error of treatment and outcomes exhibit a bound:*

$$\sqrt{N} \lambda_N \equiv \max_{1 \leq j \leq d} |G_N(\hat{d}_j(Z_{it}) - d_{0,j}(Z_{it}))|^2 \lesssim_P o_P(1)$$

$$\sqrt{N} \lambda_N \equiv \max_{1 \leq j \leq d} |G_N(\hat{d}_j(Z_{it}) - d_{0,j}(Z_{it}))(\hat{l}(Z_{it}) - l_{0}(Z_{it}))| \lesssim_P o_P(1)$$

**Assumption 3.3** (LLN for Matrices for m.d.s). *Let $(\tilde{D}_{mt})_{mt=(1,1)}^{G,T}$ be a stationary process with bounded realizations, whose dimension $d = d(N)$ grows. Let*

$$Q \equiv E \tilde{D}'_{mt} \tilde{D}_{mt}$$

$$\|E \tilde{D}'_{mt} \tilde{D}_{mt} - Q\| \lesssim_P \sqrt{d \log N \over N}$$

Assumption 3.3 has been shown for the case of i.i.d case by ([Rudelson, 1999]). Combining his arguments with blocking methods, we can show that it continues to hold under exponential mixing condition for panel data.

**Assumption 3.4.** Let $Q \equiv E \tilde{D}'_{mt} \tilde{D}_{mt}$ denote population covariance matrix of treatment residuals. Assume that $\exists 0 < C_{\min} < C_{\max} < \infty$ s.t. $C_{\min} < \min \text{eig}(Q) < \max \text{eig}(Q) < C_{\max}$. 

**Assumption 3.5.** The following conditions hold.

1. $\|\tilde{D}_{mt}\| \leq D < \infty$
2. *Lindeberg Condition:* $E\|U_{mt}U_{mt}'\|1_{\|U_{mt}U_{mt}'\| > M} \to 0, M \to \infty$

Assumption 3.4 requires that the treatments $\tilde{D}_{mt}$ are not too collinear, allowing identification of the treatment effect $\beta_0$. Assumption 3.5 imposes technical conditions for asymptotic theory. Since a bounded treatment $\tilde{D}_{mt}$ is a plausible condition in practice, we impose it to simplify the analysis. In addition, we require the disturbances $U_{mt}$ to have light tails as stated in Lindeberg condition.
3.2 Low Dimensional Treatments

In this section we consider Low-Dimensional (LD) case: \( d = o(N/\log N) \). We define Orthogonal Least Squares and state its asymptotic theory.

**Definition 3.1 (Orthogonal Least Squares).** Given first stage estimators \( \hat{d}, \hat{l} \), define Orthogonal Least Squares estimator:

\[
\hat{\beta} = E_N [D_{it} - \hat{d}(Z_{it})][D_{it} - \hat{d}(Z_{it})]'^{-1}E_N [D_{it} - \hat{d}(Z_{it})][Y_{it} - \hat{l}(Z_{it})]' = Q^{-1}E_N (\hat{D}_{it} \hat{Y}_{it}),
\]

where the second and third lines implicitly define estimators of residualized vectors and matrices.

Orthogonal Least Squares is our first main estimator. As suggested by its name, it performs ordinary least squares on estimated treatment and outcome residuals, that are approximately orthogonal to the realizations of the controls. In case the dimension \( d \) is fixed, it coincides with Double Machine Learning estimator of [Chernozhukov et al., 2016]. Allowing dimension \( d = d(N) \) to grow with sample size is a novel feature of this paper.

**Assumption 3.6 (Dimensionality Restriction).**

(a) \( \exists C > 0 \quad \forall j \in \{1, 2, ..., d\} \mid \beta_{0,j} \mid < C \)

(b) For the quality parameter \( \delta > 0 \) defined in Assumption 3.1, \( d = o(N^{4\delta/3}) \)

Assumption 3.6 imposes growth restrictions on the treatment dimension. The first restriction ensures that every components of the true treatment vector is bounded. The second restriction \( d = o(N^{4\delta/3}) \) defines the treatment growth rate relative to the quality of the first stage treatment estimator.

**Theorem 3.1 (Orthogonal Least Squares).** Let Assumptions 3.3, 3.4, 3.5, and 3.6 hold.

(a)

\[
\| \hat{\beta} - \beta \|_2 \lesssim_P \sqrt{\frac{d}{N}} + d m_N^2 \| \beta_0 \| + l_N \sqrt{d} m_N + \sqrt{d/N} \sqrt{d} m_N \| \beta_0 \|
\]

Let Assumption 3.1 hold for the statements below. Then,

\[
\| \hat{\beta} - \beta \|_2 \lesssim_P \sqrt{\frac{d}{N}}
\]

13
(b) For any $\alpha \in S^{d-1}$
\[
\sqrt{N} \alpha' (\hat{\beta} - \beta) = \alpha' Q^{-1} G_N \tilde{D}_t U_t + R_{1,N}(\alpha)
\]
where $R_{1,N}(\alpha) \lesssim P \sqrt{N} \sqrt{d_m l_N} + \sqrt{N} d_m^2 \|\beta_0\| + \sqrt{d l_N} + d_m N \|\beta_0\|
\
(c) Denote
\[
\Omega = Q^{-1} E \tilde{D}'_{mt} U_{mt} U_{mt}' \tilde{D}_{mt} Q^{-1}
\]
Then, $\forall t \in \mathcal{R}$ and for any $\alpha \in S^{d-1}$
\[
\lim_{N \to \infty} \left| P \left( \frac{\sqrt{N} \alpha' (\hat{\beta} - \beta_0)}{\|\alpha' \Omega\|^{1/2}} < t \right) - \Phi(t) \right| = 0. \tag{3.1}
\]

Theorem 3.1 is our first main result. Under small bias condition, OLS attains oracle rate and has oracle asymptotic linearity representation. Under Lindeberg condition, OLS is asymptotically normal with asymptotic variance $\Omega$, which can be consistently estimated by White cluster-robust estimator
\[
\hat{\Omega} = \hat{Q}^{-1} E \tilde{D}'_{mt} U_{mt} U_{mt}' \tilde{D}_{mt} \hat{Q}^{-1},
\]
where $\hat{U}_{mt} \equiv (\hat{Y}_{mt} - \hat{D}'_{mt} \hat{\beta})$. The asymptotic variance $\Omega$ is not affected by first stage estimation.

3.3 High Dimensional Sparse Treatments

In this section we consider a High-Dimensional Sparse case $d = d(N) > N$. We state a finite-sample bound on the rate of Orthogonal Lasso. We define a Debiased Orthogonal Lasso and provide its asymptotic linearization. This allows to conclude about its Gaussian approximation of a single coefficient (Central Limit Theorem) and many coefficients (Central Limit Theorem in High Dimension).

3.3.1 Lasso in High Dimensional Sparse Case

Here we introduce the basic concepts of high-dimensional sparse literature. We allow for our parameter of interest $\beta_0 \in \mathcal{R}^d$ to be high-dimensional $(d = d(N) > N)$ sparse. Let $s_N$ be the sparsity of $\beta_0$: $\|\beta_0\|_0 = s_N$. Let the set of active regressors be $T \equiv \{ j \in \{1, 2, ..., d \}, \text{s.t.} \beta_{0,j} \neq 0 \}$. For a given $\tilde{c} \geq 1$, let the set $\mathcal{RE}(\tilde{c}) \equiv \{ \delta \in \mathcal{R} : \|\delta_T\|_1 \leq \tilde{c} \|\delta_T\|_1, \delta \neq 0 \}$ be a restricted subset of $\mathcal{R}^d$. 

Let the sample covariance matrix of true residuals be $\tilde{Q} \equiv E_N \tilde{D}_m't \tilde{D}_m$. Let the in-sample prediction norm be: $\| \delta \|_{2,N} = (E_N (\tilde{D}_m' \delta)^2)^{1/2}$. Define Restricted Eigenvalue of covariance matrix of true residuals:

$$\kappa(\tilde{Q}, T, \bar{c}) := \min_{RE(\bar{c})} \frac{\sqrt{s} \delta'^T \tilde{Q} \delta}{\| \delta_T \|_1} = \min_{RE(\bar{c})} \frac{\sqrt{s} \| \delta \|_{2,N}}{\| \delta_T \|_1}$$

(3.2)

**Assumption 3.7 (RE(\bar{c})).** For a given $\bar{c} > 1$, Restricted Eigenvalue is bounded from zero:

$$\kappa(\tilde{Q}, T, \bar{c}) > 0$$

Assumption 3.7 has been proven for i.i.d. case by [Rudelson and Zhou, 2013]. We assume that it holds under plausible weak dependence conditions.

**Definition 3.2 (Orthogonal Lasso).** Let $\lambda > 0$ be a constant to be specified.

$$\hat{Q}(b) = E_N (\tilde{Y}_{it} - \tilde{D}_{it}b)^2$$

$$\hat{\beta}_L = \arg \min_{b \in \mathbb{R}^k} \hat{Q}(b) + \lambda \| \beta \|_1$$

(3.3)

Orthogonal Lasso is our second main estimator. It performs $l_1$ penalized least squares minimization using the outcome residual $\tilde{Y}_{it}$ as dependent variable and the treatment residuals $\tilde{D}_{it}$ as covariates. The regularization parameter $\lambda$ controls the noise of the problem. Its choice is described below.

We summarize the noise with the help of two metrics. The first one, standard for Lasso literature, is the maximal value of the gradient coordinate of $\hat{Q}(\cdot)$ at the true value $\beta_0$

$$\| S \|_\infty \equiv 2 \| E_N \tilde{D}_{it}'(\tilde{Y}_{it} - \tilde{D}_{it}\beta_0) \|_\infty$$

The second one is the maximal entry-wise difference between covariance matrices of true and estimated residuals

$$q_N \equiv \max_{1 \leq m,j \leq d} | \tilde{Q} - \hat{Q} |_{m,j}.$$ 

It summarizes the noise in the covariates due to first-stage approximation error. Both quantities can be controlled by the first stage convergence and concentration rates in Assumption 3.1 and 3.2, applying Azouma-Hoeffding maximal inequality.

To control the noise, the parameter $\lambda$ should satisfy: $\lambda \geq c \| S \|_\infty$. Asymptotically, for this to happen it suffices for $\lambda$ to be determined by the following condition.
Condition 3.1 (OPT). Fix a constant $c > 0$ to be specified. Let $\lambda$ be chosen as follows:

$$\lambda = c\left[ l_N m_N \vee s m_N^2 \vee \lambda_N \right]$$

Theorem 3.2 (Orthogonal Lasso). Suppose $\exists c > 1$ such that Assumption RE($\bar{c}$) holds for $\bar{c} = (c + 1)/(c - 1)$. Let $N$ be sufficiently large such that

$$q_N(1 + \bar{c})^2 s/\kappa(\tilde{Q}, T, \bar{c})^2 < 1/2$$

(a) If $\lambda \geq c||S||_{\infty}$, $\|\hat{\beta}_L - \beta_0\|_{N,2} \leq 2\lambda \frac{s}{\kappa(\tilde{Q}, T, \bar{c})}$

(b) If $\lambda \geq c||S||_{\infty}$ and RE($2\bar{c}$) holds, $\|\hat{\beta}_L - \beta_0\|_1 \leq 2\lambda \frac{s}{\kappa(\tilde{Q}, T, 2\bar{c})\kappa(\tilde{Q}, T, \bar{c})}$

(c) Suppose $\lambda$ is as in Condition OPT. As $N$ grows,

$$\|\hat{\beta}_L - \beta_0\|_{N,2} \lesssim_P \sqrt{s} \left[ \lambda_N \vee l_N m_N \vee s m_N^2 \vee \bar{\sigma} \sqrt{\log d/N} \right]$$

(d)

$$\|\hat{\beta}_L - \beta_0\|_1 \lesssim_P s \left[ \lambda_N \vee l_N m_N \vee s m_N^2 \vee \bar{\sigma} \sqrt{\log d/N} \right]$$

This is our second main result in the paper. The statements (a,b) establish finite-sample bounds on $\|\hat{\beta}_L - \beta_0\|_{N,2}$ and $\|\hat{\beta}_L - \beta_0\|_1$ for a sufficiently large $N$. The statements (c,d) establish asymptotic bounds on $\|\hat{\beta}_L - \beta_0\|_{N,2}$ and $\|\hat{\beta}_L - \beta_0\|_1$. Under small bias and concentration conditions (Assumptions 3.1 and 3.2), the asymptotic bounds coincide with respective bounds of oracle lasso (see e.g., [Belloni and Chernozhukov, 2013]).

The total bias of $\hat{\beta}_L$ scales with sparsity $s$, not the total dimension $d$. This is a remarkable property of $l_1$ penalization. It forces $\hat{\beta} - \beta_0$ to belong to $\mathcal{RE}(\bar{c})$, where the total bias scales in proportion to the bias accumulated on the active regressors. This ensures convergence of Lasso in the regime $d = d(N) > N$.

Remark 3.1 (Comparison of Baseline Lasso and Orthogonal Lasso in a Linear Model). Suppose the function $g(Z)$ in Equation 2.9 is a linear and sparse in $Z$:

$$g(Z) = Z'\gamma, \quad ||\gamma||_0 = s_{\gamma,N} = s_{\gamma} < N$$

and the treatment reduced form is linear and sparse in $Z$

$$d_k(Z) = Z'\delta_k, \quad ||\delta||_0 = s_\delta < s_{\gamma}, k \in \{1, 2, ..., d\}$$
In this problem, a researcher has a choice between running one-stage Baseline Lasso, where the covariates consist of the treatments \( D \) and the controls \( Z \), and the Orthogonal Lasso, where the controls are partialled out first.

Let us describe an empirically relevant scenario in which Orthogonal Lasso has a faster rate. Let the complexity of treatments be smaller than the complexity of the controls:

\[
\frac{s^2 \log d}{s^2 \gamma \log p} = o(1)
\]

Define Baseline Lasso as

\[
\hat{\beta}_B = \arg \min_{(\beta, \gamma)} \hat{Q}(\beta, \gamma) + \lambda_\beta \|\beta\|_1 + \lambda_\gamma \|\gamma\|_1
\]

In case \( \mathbb{E}D_{it}Z_{it} \neq 0 \), estimation error of \( \hat{\gamma} \) has a first order effect on the gradient of \( \hat{Q}(\beta, \gamma) \) with respect to \( \beta \), and therefore, the bias of \( \hat{\beta} - \beta_0 \) itself. Therefore, an upper bound on \( \|\hat{\beta}_B - \beta_0\|_1 \) of the baseline Lasso

\[
\|\hat{\beta}_B - \beta_0\|_1 \lesssim_P \|\hat{\gamma} - \gamma_0\|_1 \lesssim_P \sqrt{\frac{s^2 \log p}{N}}
\]

By contrast,

\[
\|\hat{\beta}_L - \beta_0\|_1 \lesssim_P \frac{s_\gamma s_\delta \log p}{N} + \frac{ss_\delta \log p}{N} + \sqrt{\frac{s^2 \log d}{N} \bar{\sigma}}
\]

Therefore, the estimation error of \( \hat{\gamma} \) has a second order effect on the rate of \( \hat{\beta}_L \). Since the complexity of controls is larger than the complexity of the treatment, the error of \( \hat{\gamma} \) determines the rate of both estimators. Reducing its impact on \( \hat{\beta}_L \) from first order in \( \hat{\beta}_B \) to second order in \( \hat{\beta}_L \) by projecting the outcome and treatments on the orthocomplement of \( Z \) gives rate improvement.

### 3.3.2 Inference in High Dimensional Sparse case

After we have established the properties of Orthogonal Lasso, we propose a debiasing strategy that will allow us to conduct inference in HDS case. We will employ the following assumption.

**Assumption 3.8 (Approximate sparsity of \( Q^{-1} \)).** Let \( Q = \mathbb{E}\tilde{D}'_{mt}\tilde{D}_{mt} \) be the population covariance matrix. Assume that there exists a sparse matrix \( M = [m_1, ..., m_d]' \):

\[
\frac{s^2 \log d}{s^2 \gamma \log p} = o(1)
\]
that is a good approximation for inverse of matrix $Q^{-1}$:

$$\|Q^{-1} - M\|_{\infty} \lesssim \sqrt{\frac{\log d}{N}}$$

Assumption 3.8 restricts a pattern of correlations between treatment residuals. Examples of matrices $Q$ satisfying Assumption 3.8 include Toeplitz, block diagonal, and band matrices. In addition, if dimension $d$ and the rate $m_N$ satisfy $dN m_N^2 = o(1)$, any invertible matrix $Q$ satisfies Assumption 3.8 with $M = Q^{-1}$.

**Condition 3.2 (Approximate Inverse of $\hat{Q}$).** Let $a$ be a large enough constant, and let $\mu_N \equiv a \sqrt{\frac{\log d}{N}}$. Let $\hat{Q} = \mathbb{E}_N \hat{D}_{mt} \hat{D}_{mt}$. A matrix $M = [m_1, ..., m_d]'$ approximately inverts $\hat{Q}$ if for each row $j \in \{1, 2, ..., d\}$ $\|\hat{Q}m_j - e_j\|_{\infty} \leq \mu_N$

**Definition 3.3 (Constrained Linear Inverse Matrix Estimation).** Let $M = M(\hat{Q}) = [m_1, ..., m_d]'$ solve

$$m_j^* = \arg\min \|m_j\|_1 \ s.t. \ \|\hat{Q}m_j - I_d\|_{\infty} \leq \mu_N \forall j \in \{1, 2, ..., d\}$$

We will refer to $M(\hat{Q})$ as CLIME.

Condition 3.2 introduces a class of matrices that approximately invert the covariance matrix $\hat{Q}$ of estimated residuals. By Lemma C.1, this class contains all matrices that approximately invert $Q$ (including precision matrix $Q^{-1}$), and therefore is non-empty. Within this class, we focus on the matrix with the smallest first norm, which we refer to as CLIME of $\hat{Q}$. Due to proximilty of $\hat{Q}$ to $Q$, CLIME of $\hat{Q}$ consistently estimates the precision matrix $Q^{-1}$ at rate $\sqrt{\frac{\log d}{N}}$ in elementwise norm.

Once we introduced an estimate of $Q^{-1}$, let us explain the debiasing strategy in the oracle case. Let $\hat{\beta}_L$ be the (oracle) Orthogonal Lasso estimate of the treatment effect $\beta_0$ and $\tilde{U}_{it} := \hat{Y}_{it} - \hat{D}_{it}' \hat{\beta}_L$ be oracle Lasso residual. Let $j \in \{1, 2, ..., d\}$ be the treatment effect of interest and $m_j$ be the $j$'th row of the approximate inverse $M$. Recognize that Lasso residual $\tilde{U}_{it}$ consists of the true residual $U_{it}$ and the fitting error $\hat{D}_{it}'(\beta_0 - \hat{\beta})$

$$\tilde{U}_{it} = U_{it} + \hat{D}_{it}'(\beta_0 - \hat{\beta})$$
Therefore, the correction term
\[
\sqrt{N} m_j' E_N \tilde{D}_i U_{it} = m_j' G_N \tilde{D}_i U_{it} + \sqrt{N} m_j' \tilde{Q} (\hat{\beta}_0 - \hat{\beta})
\]
\[= S_j + \sqrt{N} m_j' E_N \tilde{D}_i U_{it} + \sqrt{N} m_j' \tilde{Q} (\hat{\beta}_0 - \hat{\beta})
\]
where \(S_j\) is approximately normally distributed and \(\Delta\) is the remainder. By definition of approximate inverse \(m_j' \tilde{Q} \approx e_j\), \(\Delta\) offsets the bias of Orthogonal Lasso up to first-order:
\[\Delta \approx \sqrt{N} (\beta_0,j - \hat{\beta}_L,j) + o_P(1).\]
Adding this correction term to the original Lasso estimate \(\hat{\beta}_{L,j}\) returns unbiased, asymptotically normal estimate:
\[
\sqrt{N} \left[ \hat{\beta}_{DOL,j} - \beta_0,j \right] = S_j + \sqrt{N} m_j' E_N \tilde{D}_i U_{it} + \sqrt{N} m_j' \tilde{Q} (\hat{\beta}_0 - \hat{\beta})
\]
\[= S_j + o_P(1/\sqrt{N}) \quad (3.7)
\]
Let us see that the debiasing strategy is compatible with first stage error. In presence of the latter, Equation 3.7 becomes
\[
\sqrt{N} \left[ \hat{\beta}_{DOL,j} - \beta_0,j \right] = S_j + \sqrt{N} m_j' E_N \tilde{D}_i U_{it} + \sqrt{N} m_j' \tilde{Q} (\hat{\beta}_0 - \hat{\beta}_L) + \Delta^f s
\]
\[= S_j + o_P(1/\sqrt{N})
\]
Since the true residual is mean independent from first-stage approximation error, the bias of the vector \(E_N [\tilde{D}_i U_{it} + R_{it}] - \tilde{D}_i U_{it}\) is second-order. Small bias and concentration assumptions 3.1 and 3.2 ensure that worst-case first-stage error is small
\[
\max_{1 \leq j \leq d} \left| E_N [\tilde{D}_i U_{it} + R_{it}] - \tilde{D}_i U_{it} \right| = \sqrt{\log d \over N} + \lambda_N + m_N^2 s \lor l_N m_N
\]
To conclude \(\Delta^f s\) is small, let us see that the rows of matrix \(M\) are approximately sparse. Each row \(m_j\) can be approximated by a sparse vector \(m_j^0\) of sparsity \(m_0\) such that \(\|m_j - m_j^0\|_1 \lesssim 2m_0 \sqrt{\log d \over N}\). The sparsity of \(m_j^0\) suffices to conclude
\[
\Delta^f s = \sqrt{N} [m_j^0 + m_j - m_j^0] E_N [\tilde{D}_i U_{it} + R_{it}] - \tilde{D}_i U_{it}
\]
\[= o_P(m_0[1 + \sqrt{\log d \over N}] [\sqrt{\log d \over N} + \lambda_N + m_N^2 s \lor l_N m_N])
\]
\[= o_P(1)
\]
After we have explained the debiasing strategy, we proceed to definition of Debiased Orthogonal Lasso.
**Definition 3.4** (Debiased Orthogonal Lasso). Let $M$ be CLIME of $\hat{Q}$. Then,

$$\hat{\beta}_{DOL} \equiv ME_N \hat{D}_{it}(\hat{Y}_{it} - \hat{D}_{it}\hat{\beta}_L) + \hat{\beta}_L \tag{3.8}$$

In case dimension $d = o(1/[\sqrt{Nm_N^2} + \sqrt{Nm_N}|\lambda])$ grows at a small rate, Assumption 3.8 is always satisfied: one can pick $M = (\hat{Q} + \gamma I_d)^{-1}$ to be regularized inverse of $\hat{Q}$. This gives rise to a simple asymptotically normal estimator we refer to as Debiased Orthogonal Ridge.

**Definition 3.5** (Debiased Orthogonal Ridge). Let $d \equiv o(1/\sqrt{Nm_N^2} + \sqrt{Nm_N}|\lambda])$. Let $\gamma > 0, \gamma \lesssim \sqrt{\log d N}$ be a regularization constant. Define debiased Ridge estimator by choosing $M \equiv (\hat{Q} + \gamma I_d)^{-1}, \gamma \geq 0$ as a regularized inverse in Debiased Orthogonal Lasso:

$$\hat{\beta}_{Ridge} \equiv ME_N \hat{D}_{it}(\hat{Y}_{it} - \hat{D}_{it}\hat{\beta}_L) + \hat{\beta}_L \tag{3.9}$$

**Theorem 3.3** (Debiased Orthogonal Lasso and Debiased Orthogonal Ridge). Let $M$ be chosen as in Definition 3.4 or 3.5. Let Assumptions 3.5, 3.4, 3.1, 3.8 hold.

(a) For any $j \in \{1, 2, \ldots, d\}, \sqrt{N}(\hat{\beta}_j - \beta_{j,0}) = G_{N,M}\hat{D}_{it}'U_{it} + R_{1,N,j}$

where $\sup_{1 \leq j \leq d} |R_{1,N,j}| = o_P(1)$

(b) Denote

$$\Omega = ME_N \hat{D}_{it}'U_{it}' \hat{D}_{mt} M'$$

Then, $\forall t \in \mathcal{R}$

$$\lim_{N \to \infty} \left| \mathbb{P}\left( \frac{\sqrt{N}(\hat{\beta}_j - \beta_{j,0})}{\Omega_{jj}} < t \right) - \Phi(t) \right| = 0. \tag{3.10}$$

Theorem 3.3 is our third main result. Under Assumptions 3.1 and 3.2, for all $j \in \{1, 2, \ldots, d\}$ $\hat{\beta}_{DOL,j}$ and $\hat{\beta}_{Ridge,j}$ are asymptotically linear. Under Lindeberg condition, each of them is asymptotically normal with oracle covariance matrix

$$\Omega = ME_N \hat{D}_{it}'U_{it}' \hat{D}_{mt} M'.$$

This matrix can be consistently estimated by

$$\hat{\Omega} = ME_N \hat{D}_{it}'\hat{U}_{it}'\hat{D}_{mt} \hat{M}.$$
where \( \hat{U}_{mt} \equiv \hat{Y}_{mt} - \hat{D}_{mt}'\hat{\beta}_L \).

In absence of first-stage estimation error (oracle case), any matrix \( M \) that approximately inverts \( \hat{Q} \) can be used to construct a debiased, asymptotically normal estimator. For example, [Javanmard and Montanari, 2014] suggest variance minimizing choice of \( M \) in oracle case. In contrast to their design, we have the first-stage bias to control for. We achieve our goal by choosing sparse \( M \).

**Theorem 3.4** (Gaussian Approximation and Simultaneous Inference on Many Coefficients). Suppose the conditions in the previous theorem hold, and \( \sqrt{N} \text{m}_N l_N \vee \sqrt{N} \text{m}_N^2 = o(1/\log d) \) holds in addition. Then, we have the following Gaussian approximation result

\[
\sup_{R \in \mathbb{R}} |P((\text{diag } \hat{\Omega})^{-1/2} \sqrt{N}(\hat{\beta}_{DOL} - \beta) \in R) - P(Z \in R)| \rightarrow 0
\]

where \( Z \sim N(0, C) \) is a centered Gaussian random vector with covariance matrix \( C = (\text{diag } \Omega)^{-1/2}\Omega(\text{diag } \Omega)^{-1/2} \) and \( R \) denotes the collection of cubes in \( \mathbb{R}^d \) centered at the origin. Moreover, replacing \( C \) with \( \hat{C} = (\text{diag } \hat{\Omega})^{-1/2}\hat{\Omega}(\text{diag } \hat{\Omega})^{-1/2} \) we also have for \( \tilde{Z} | \tilde{C} \sim N(0, \hat{C}) \)

\[
\sup_{R \in \mathbb{R}} |P((\text{diag } \hat{\Omega})^{-1/2} \sqrt{N}(\hat{\beta}_{DOL} - \beta) \in R) - P(\tilde{Z} \in R | \tilde{C})| \rightarrow_p 0.
\]

Consequently, for \( c_{1-\xi} = (1 - \xi)\)-quantile of \( \|\tilde{Z}\|_\infty | \tilde{C} \), we have that

\[
P(\beta_{0,j} \in [\hat{\beta}_{DOL,j} \pm c_{1-\xi} \hat{\Omega}_{jj}^{1/2} N^{-1/2}], j = 1, 2..., d) \rightarrow (1 - \xi).
\]

This first result follows as a consequence of the Gaussian approximation result of [Zhang and Wu, 2015] for time series, and the second by the Gaussian comparison inequalities of [Chernozhukov et al., 2015], and Theorem 4.2 establishes a uniform bound on \( \|\hat{\Omega}_{jj} - \Omega_{jj}\|_\infty \). As in [Chernozhukov et al., 2013a], the Gaussian approximation results above could be used not only for simultaneous confidence bands but also for multiple hypothesis testing using the step-down methods.

### 4 Sufficient Conditions for First Stage Estimators

In this section we describe the plausibility of first stage conditions, discussed in Section 3.
4.1 Affine Structure of Treatments

Here we discuss a special structure of treatments that allows us to simplify high level assumptions of Section 3 and reduce computational time. Suppose there exists an observable base treatment variable $P$ and a collection of known maps $\{\Omega_k = \Omega_k(Z) : Z^p \rightarrow \mathcal{R}^{d_p}\}$, such that every treatment $D_k = \Omega_k(Z)P, k \in \{1, 2, \ldots, d\}$ is an affine transformation of the base treatment. In case $d > 1$, an estimate of the reduced form of the base treatment $p_0(Z)$ can be used to construct an estimate $\hat{d}_i(Z) = \Omega_k(Z_i)\hat{p}_i(Z_i)$. Lemma 4.1 shows the simplification of the conditions.

Lemma 4.1 (Affine Treatments). Suppose a first-stage estimator of $p_0(Z_i)$, denoted by $\hat{p}(Z)$, belongs w.h.p to a realization set $P_N$ constrained by the rates $m_N, r_N, \lambda_N$. Then, an estimator $\hat{D}(Z)$ of $d_0(Z)$, defined as

$$\hat{D}_k(Z) \equiv \Omega_k(Z)\hat{p}(Z), \quad k \in \{1, 2, \ldots, d\}$$

belongs to a realization set $D_N$ that contains the true value of $d_0(Z)$ and achieves the same treatment rate, mean square rate, and concentration rate as original $\hat{p}(Z)$, regardless of dimension $d$.

Lemma 4.1 shows that Assumptions 3.1 and 3.2 about the technical treatment $D_{it}$ hold if and only if Assumptions 3.1 and 3.2 hold for the base treatment $P_{it}$. Therefore, the treatment rate and concentration rates are now free from dimension $d$. Both Examples 1 and 2 have affine treatment structure.

4.2 Dependence Structure of Observations

Here we discuss special structure of individual heterogeneity that allows us to verify Assumptions 3.1 and 3.2. For the sake of completeness, we also provide example of cross sectional data.

Example 4 (Cross-Sectional Data). Let $T = 1$ and $(W_i)_{i=1}^T = (Y_i, D_i, Z_i)_{i=1}^T$ be an i.i.d sequence. Then, small bias condition (Assumption 3.1) is achievable by many ML methods under structured assumptions on the nuisance parameters, such $l_1$ penalized methods in sparse models ([Bühlmann and van der Geer, 2011], [Belloni et al., 2016b]) and $L_2$ boosting in sparse linear models ([Luo and Spindler, 2016]), and other methods for classes of neural nets, regression trees, and random forests ([Wager and Athey, 2016]). The bound on centered out-of-sample mean squared error in Assumption 3.2 follows from Hoeffding inequality.
**Example 5** (Panel Data (No Unobserved Heterogeneity)). Let \( \{W_{it}\}_{t=1}^{T} \) be an i.i.d sequence. Let the reduced form of treatment and outcome be:

\[
\begin{align*}
    d_{i0}(Z_{it}) &= d_0(Z_{it}) \\
    l_{i0}(Z_{it}) &= l_0(Z_{it})
\end{align*}
\]

In other words, there is no unobserved unit heterogeneity. Then, the small bias condition is achieved by many ML methods. Assumption 3.2 holds under plausible \( \beta \)-mixing conditions on \( Z_{it} \) (see e.g. [Chernozhukov et al., 2013b].)

**Remark 4.1** (Partialling out individual heterogeneity). Partialling out unobserved item heterogeneity may be a desirable step in case one wants to model it in a fully flexible way. However, applying the described estimators on the partialled out data leads to the loss of their oracle properties in a dynamic panel model. In particular, plug-in estimators of asymptotic covariance matrices of Orthogonal Least Squares and debiased Ridge will be inconsistent.  

### 4.2.1 Weakly Sparse Unobserved Heterogeneity

Consider the setup of Example 2. Let the sales and price reduced form be

\[
\begin{align*}
    l_{i0}(Z_{it}) &= l_0(Z_{it}) + \xi_i \\
    p_{i0}(Z_{it}) &= p_0(Z_{it}) + \eta_i
\end{align*}
\]

where the controls \( Z_{it} \equiv [Y_{i,t-1}, Y'_{i,t-2}, \ldots, Y'_{i,t-L}, P'_{i,t-1}, P'_{i,t-2}, \ldots, P'_{i,t-L}, X_{it}] \) include all pre-determined and exogenous observables observed for item \( i \), relevant for predicting the reduced form and \( \xi_i, \eta_i \) is unobserved time-invariant heterogeneity of product \( i \). Following Example 3, we project \( \xi_i, \eta_i \) on space of time-invariant observables \( \bar{Z}_i \):

\[
\begin{align*}
    \lambda_0(\bar{Z}_i) &\equiv \mathbb{E}[\xi_i|\bar{Z}_i] \quad \text{and} \quad \gamma_0(\bar{Z}_i) \equiv \mathbb{E}[\eta_i|\bar{Z}_i]
\end{align*}
\]

We assume that \( \bar{Z}_i \) contains sufficiently rich product descriptions such that \( a_i \equiv \xi_i - \lambda_0(\bar{Z}_i) \) and \( b_i = \eta_i - \gamma_0(\bar{Z}_i) \) are small. We impose weak sparsity assumption: (see, e.g.

---

7 Partialling out unobserved heterogeneity in a high-dimensional sparse model was considered in [Belloni et al., 2016a].

8 This specification of the controls implicitly assumes that conditional on own demand history, the price and sales of item \( i \) are independent from the demand history of the other members of group \( g_i \). If this assumption is restrictive, one can re-define the controls to include all relevant information for predicting \( (Y_{it}, P_{it}) \).
\[ \exists \quad s < \infty \quad 0 < \nu < 1 \quad \sum_{i=1}^{N} |a_i|^\nu \leq s \]
\[ \sum_{i=1}^{N} |b_i|^\nu \leq s \]

Under this assumption, the parameters to be estimated are the functions \( l_0, \lambda_0, p_0, \gamma_0 \) and the vectors \( a = (a_1, ..., a_N)' \) and \( b = (b_1, ..., b_N)' \). Assume that the price and sales reduced form is a linear function of observables
\[ l_0(Z_{it}) = E[Y_{it}|Z_{it}] = [Z_{it}, \bar{Z}_i]' \gamma^Y + a_i \]
\[ p_0(Z_{it}) = E[P_{it}|Z_{it}] = [Z_{it}, \bar{Z}_i]' \gamma^P + b_i \]

where the parameters \( \gamma^Y, \gamma^P \) are high-dimensional sparse parameters. Consider the dynamic panel Lasso estimator of Kock-Tang:
\[
(\hat{\gamma}_k^D, \hat{a}_k) = \sum_{(i,t) \in I_k} (D_{it} - Z_{it}' \gamma^D - a_i)^2 + \lambda \| \gamma^D \|_1 + \frac{\lambda}{\sqrt{N}} \| a \|_1
\]
and
\[
(\hat{\gamma}_k^Y, \hat{b}_k) = \sum_{(i,t) \in I_k} (Y_{it} - Z_{it}' \gamma^Y - b_i)^2 + \lambda \| \gamma^Y \|_1 + \frac{\lambda}{\sqrt{N}} \| b \|_1
\]

Let the respective reduced form estimate be:
\[ \hat{p}(Z_{it}) = Z_{it}' \hat{\gamma}^D + \hat{b}_i \]
\[ \hat{I}(Z_{it}) = Z_{it}' \hat{\gamma}^Y + \hat{a}_i \]

**Remark 4.2** (Rate of dynamic panel lasso). In case \( C = 1 \), under mild conditions on the design of \( (Y_{it}, P_{it})_{t=1}^{G,T} \) Theorem 1 of [Kock and Tang, 2016] implies that first stage rates \( m_N = l_N = \frac{\log^{3/2}(p \nu T) s_1}{\sqrt{TT}} \sqrt{s_1 \frac{1}{\sqrt{T}}} (\frac{\lambda s_1}{\sqrt{T}})^{1-\nu} = o((N)^{-1/4}) \), where \( s_1 \) is a bound on the sparsity of \( \gamma^P, \gamma^Y \). If the weak sparsity measure of unobserved heterogeneity \( s \) is sufficiently small, Assumption 3.1 holds. By Corollary E.1 one can always take \( \lambda_N = m_N^2 = o(1/\sqrt{N}) \) in Assumption 3.2. We expect Assumption 3.1 to hold for any cluster size \( C \), but proving this is left as future work.
5 Empirical Application To Demand Estimation

In this section, we apply our estimators to measure own and cross-price elasticities faced by a major food distributor that sells to retailers. This distributor provided us with a sample of their transactional data containing all sales data from a number of major branches and spanning approximately four years. The data consists of a weekly time series of price and units sold for each of 4,673 unique products in each of eleven locations, and for each of three delivery channels. In total, our data includes almost two million weekly observations.

Furthermore, we have access to detailed product descriptions that we used to construct a hierarchical categorization for each product which is then included in our dataset. Our hierarchy goes up to five levels deep, but we will only provide names for the first two levels (which we refer to as Level 1 and Level 2 categories). These are presented in Table 1.

The data contains frequent variation in price as products cycle on and off of promotion on a regular cadence. Such variation in price may be correlated with expectations about demand. So, it is critical that our first stage estimators accurately capture forward looking expectations of price setters so that we are not be contaminated by endogeneity. Such concerns are generally untestable. However, we also have access to a subset of data in which the distributor agreed to randomize prices across two locations. This randomization allows us to experimentally validate the elasticities learned in the broader data set. This final analysis is presented in Section 5.3.

---

| Level 0 Category | Drinks | Household Items | Other Food | Protein |
|------------------|--------|-----------------|------------|---------|
| Level 1 Categories | Water | Tableware | Sweets | Dairy |
| | Soda | Sanitation | Snacks | Seafood |
| | Adult Beverages | Boxes | Sugar | Red Meat |
| | | Stationary | Veggies | Chicken |

Table 1: First two levels of hierarchical categorization for products used in this analysis.

---

9 Customers can shop online or via telesales for same-day, collection or next-day delivery, with each such combination constituting a separate channel.

10 In order to preserve any threat to the anonymity of the distributor, we have altered the names of some of these categories (without changing meaning) and we will not report the names of any lower level categories.
5.1 Demand Model

Let each unique combination of product, delivery channel, and store be indexed by \( i \) and let the corresponding log sales and log price in week \( t \) be denoted by \( Q_{i,t} \) and \( P_{i,t} \), respectively. Let \( \{H_k\}_{k=1}^K \) be a collection of sets, corresponding to our hierarchical categorization of the products. See Figure 1 for an example. Here \( H_1 \) might correspond to the set “Drinks” and \( H_2 \) to the set “Soda”. Additionally, we may refer to different levels of our hierarchy to identify some sub-collection of these sets. For example, Drinks are a Level 1 category, whereas Water and Soda are Level 2 categories. Leaf nodes (e.g. S. Pellegrino) are not individual products, but rather, the finest level of categorization in which multiple products are still included.\(^{11}\)

![Figure 1: An example of a hierarchical categorization that is used to classify products. Leaf nodes should be viewed as the individual products and intermediate nodes at various levels of categorization.](image)

Our parameters of interest will be own-price elasticities \((\epsilon^o)\) which will be estimated heterogeneously over some subset of our hierarchy and cross-price elasticities \((\epsilon^{cp})\) which

\(^{11}\)Individual products might then be (for example) different size or packaging of S. Pellegrino bottled water. Pricing is done at the level of the individual product and so that is also the level of our modeling. However, we will not model heterogeneous elasticities at the level of the individual product in this empirical exercise due to computational constraints.
will correspond to impacts of the average non-self price within various subsets of hierarchy. We may vary which subsets of our hierarchy we used in any given specification. Formally, let $\Xi_{\text{op}}$ and $\Xi_{\text{cp}}$ denote the set of indices $k$ used to model own and cross-price elasticity, respectively, in any given specification. Then, formally, our demand model is:

$$Q_{i,t} = P_{i,t} \left( \sum_{k \in \Xi_{\text{op}}} 1_{i \in H_k} \cdot \epsilon^o_k \right) + P_{-i,k,t} \left( \sum_{k \in \Xi_{\text{cp}}} 1_{i \in H_k} \cdot \epsilon^{cp}_k \right) + g_0(Z_{i,t}) + U_{i,t}, \quad (5.1)$$

where

$$P_{-i,k,t} \equiv \frac{\sum_{j \neq i, j \in H_k} P_{j,t}}{|H_k| - 1}$$

is the average non-self in group $H_k$. The controls $Z_{i,t}$ include time, store and product fixed effects, and $L$ lagged realizations of the demand system $(Y_{i,t-l}, P_{i,t-l}) \in [l] \in \{1, 2, \ldots, L\}$ and suitably chosen interactions to maximize predictive performance of the first stage ML models. Denote the reduced form of log sales and log price, respectively, by

$$l_{i0}(z) \equiv \mathbb{E}[Q_{i,t}|Z_{i,t} = z]$$

$$p_{i0}(z) \equiv \mathbb{E}[P_{i,t}|Z_{i,t} = z]$$

Let $\hat{P}_{i,t} \equiv P_{i,t} - p_{i0}(Z_{i,t})$ and $\hat{Q}_{i,t} \equiv Q_{i,t} - l_{i0}(Z_{i,t})$ be the corresponding residuals. Intuitively, $l_{i0}$ and $p_{i0}$ may be thought of as one-period ahead, price-blind forecasts and $\hat{Q}$ and $\hat{P}$ as the corresponding deviations. Equation (5.1) implies a linear model on these deviations:

$$\hat{Q}_{i,t} = \hat{P}_{i,t} \left( \sum_{k \in \Xi_{\text{op}}} 1_{i \in H_k} \cdot \epsilon^o_k \right) + \hat{P}_{-i,k,t} \left( \sum_{k \in \Xi_{\text{cp}}} 1_{i \in H_k} \cdot \epsilon^{cp}_k \right) + U_{i,t}. \quad (5.2)$$

We estimate various specifications of this model using Orthogonalized Least Squares, Orthogonalized Lasso, and Orthogonalized Debiased Lasso as described in Sections 3.2 and 3.3. Across specifications we will vary the number of hierarchical categorizations included in $\Xi_{\text{op}}$ and $\Xi_{\text{cp}}$ in order to gauge the relative performance of our estimators under varying dimension of treatment. We will also add terms to the regression that enable us to measure heterogeneity in own-price elasticity at the monthly level in order

---

12This choice of treatment variable reflects the intuition that products who share many common levels of hierarchy are most likely to have significant cross-price effects. It further imposes the structure that strength of cross-price effects are constant within a group. Alternative, treatments could capture different proposed structures. For example, a revenue-weighted average price would correspond to a model in which consumers made choices based on independence of irrelevant alternatives within each group.
to check for seasonal patterns in price sensitivity. Results for own price elasticity are presented in Section 5.2 while results on cross-price elasticity are presented in 5.4.

5.2 Own-Price Elasticity Results

In our first specification, we estimate average elasticities across our Level 1 product categories. We run a separate estimation on each Level 1 group and the only included treatment variables are heterogeneous own-price elasticities that correspond to Level 2 categories. Since the dimension of treatment is quite small ($d \leq 4$ in all cases), we appeal to the results of our LD framework and use Orthogonal Least Squares. The resulting estimated elasticities along with 95% confidence intervals are presented in Figure 2.

![Figure 2: Average price elasticities by Level 1 category as estimated by Orthogonal Least Squares.](image)
Estimates range from the lowest \((-2.71)^{***}\) for Sodas and \((-2.12)^{***}\) for Seafood to a meager \((-0.4)^{**}\) for Tableware\(^{13}\). All product categories have elasticities that are statistically less than zero and, besides Tableware, all product categories have average elasticities less than \(-1\)^{14}.

In our next specification, we estimate heterogeneous own-price elasticity across the calendar year. Thus our treatments consist only of the own-price variable interacted with dummies for each month. Figure 3 shows the resulting estimates. Unsurprisingly, these estimates are significantly noisier and reveal only a few departures from a baseline of constant price sensitivity\(^{15}\). In particular, we do not see strong evidence of bargain-hunting behavior during holiday seasons. This is broadly consistent with the findings of Chevalier et al., 2003, however that paper studies consumer purchases in a grocery store rather than purchases from a distributor as we do. Somewhat intuitively, we did find that the elasticity of sodas is slightly closer to zero during warm months, compared to the rest of the year\(^{16}\).

Finally, we consider estimation of own-price elasticities at finer levels granularity within our hierarchy. Each of our four Level 0 groups has between 40 and 80 leaf nodes along which we might wish to estimate heterogeneity, with the number of total observations per leaf node ranging from as many as 5,000 to as few as 100. One option is to use Orthogonal Least Squares with a separate treatment interaction for each leaf node enabling us to learn independently estimated price elasticities. This would ensure unbiasedness (ignoring upstream error from our estimation of reduced forms). However, this makes no use of our hierarchical categorization and will result in very noisy estimates for leaf nodes with few observations or little idiosyncratic variation in price. If we instead suppose that the true impact of our hierarchy on product elasticity is sparse (i.e. that presence in the majority of product categories has zero added impact on elasticity), we have exactly the sparsity needed to motivate our HDS framework. As such we may prefer to use Orthogonal Lasso or Orthogonal Debiased Lasso estimators.

For purpose of comparison, we use both of these estimators as well as Orthogonal

---

\(^{13}***\), ** and * indicate statistical significance at 0.99, 0.95, 0.90 level, respectively.

\(^{14}\)The estimated elasticity of Soft Drinks is close to the elasticities of orange juice found in analysis of publicly available data from Dominick’s Finer Foods. However, this data is on consumer purchases from a retailer as opposed to the current analysis on retailer purchases from a distributor.

\(^{15}\)The biggest apparent departure is that Household Items appear to be very inelastic during the month of October. However, Household Items are a composite of two elastic Level 1 categories and one inelastic Level 1 category (Tableware) and we believe this pattern is driven by a larger than normal fraction of Tableware promotions in the October months of our data.

\(^{16}\)The estimates presented above are obtained without accounting for cross-price effects. Accounting for cross-price effects returned the estimates within one standard error of the original ones. For that reason, we exclude cross-price effects from the analysis of deeper levels of the hierarchy.
Least Squares to estimate heterogeneous own-price elasticities within the Level 1 category of Protein. We consider three different specifications in which we vary the number of levels of the hierarchy used to estimate own-price heterogeneity. Results are presented in Figure 4. Going from left to right, we start with the Orthogonal Lasso which has the greatest level of shrinkage (and therefore bias), then the Orthogonal Debiased Lasso (less shrinkage), and finally Orthogonal Least Squares (no shrinkage). The first row of this figure shows the distribution of estimated elasticities when only Levels 1 and 2 are used to estimate heterogeneity. Here the dimension of treatment is relatively small ($d = 22$) and as result, we see that the estimates of Orthogonal Least Squares are relatively plausible and that our LASSO estimators are only slightly more compressed. However, as we increase the dimension of treatment by adding all level 3 dummies ($d = 62$; see the second row) and then all Level 4 categories ($d = 77$; third row) note that the distribution of Orthogonal Least Squares estimates become increasingly dispersed and a significant number of positive (and therefore implausible) estimated elasticities are observed. By contrast, the distribution of estimated elasticities changes much less as the dimension of
treatment is increased and even in the third row does not show any positive estimated elasticities. This stability is driven by the progressively higher level of shrinkage selected by our second stage Lasso estimator. By contrast, our Orthogonal Debiased Lasso strikes a middle ground. It engages in significant shrinkage yielding less noisy (and therefore often more plausible) estimates than Orthogonal Least Squares, but it must restrict shrinkage, as compared to Orthogonal Lasso, so as to guarantee small asymptotic bias and allow for valid confidence intervals.

To better visualize how the shrinkage of the Orthogonal Lasso and Orthogonal Debiased Lasso impact our estimates, in Figure 5, we have plotted the estimated elasticities and (except for the case of Orthogonalized Lasso) associated confidence intervals for 11 selected Dairy products. Note in all cases that the Debiased Orthogonal Lasso point estimate is between the point estimates of Orthogonal Least Squares and Orthogonal Lasso. This reflects the sense that Debiased Lasso is essentially a matrix-weighted combination of OLS and Lasso as can be seen from (3.9). Moving from left to right, these products are sorted in descending order of the width of their Orthogonal Least Squares confidence interval. Note that when that confidence interval is wide, then the Debiased Lasso confidence interval is clustered around the Lasso point estimate, but as the OLS confidence intervals shrink, the Debiased Lasso estimate and confidence interval are pulled progressively towards it.

5.3 Experimental Validation of Own-Price Elasticities
Collaborating with our food distributor, we selected 40 unique product, channel combinations and agreed to run a two week promotion on each product in one of two locations. These 40 products were selected as the products for which a price cut was estimated to result in the greatest potential increase in profit, while maintaining constraints that they span all major product categories and that not two chosen products were estimated to have a significant cross-price relationship. For each product, the location of the promotion was randomly determined and the alternative location maintained prices at a baseline level.

For each of these 40 products, we then compute the own price elasticity implied by this experiment as given by

\[
\hat{\epsilon}_{exp} = \frac{(\log Q_1 - \log \hat{Q}_1) - (\log Q_2 - \log \hat{Q}_2)}{\log P_1 - \log P_2},
\]

where \(Q_s, P_s\) are the level of sales and price in location \(s\) and \(\hat{Q}_s\) is an price-blind forecast of expected sales. Additionally, we also compute \(\hat{\epsilon}_{DML}\) as the fitted elasticities from our
(a) Histogram of own-price elasticities computed allowing heterogeneous elasticities up through the second level of the hierarchy.

(b) Histogram of own-price elasticities computed allowing heterogeneous elasticities up through the third level of the hierarchy.

(c) Histogram of own-price elasticities computed allowing heterogeneous elasticities up through the fourth level of the hierarchy.

Figure 4: Histograms of own-price elasticity computed with various estimators and dimensions of treatment. Moving from left to right, the estimator used ranges from Orthogonal Lasso to Orthogonal Debiased Lasso to Orthogonal Least Squares. Moving down the rows, the dimension of treatment increases as additional layers of the product hierarchy are used to form heterogeneous treatments.
Double ML model and compare the two sets of elasticities in Figure 6. As you can see, the experimentally learned elasticities have much greater dispersion as they are learned from only a single biweekly sales outcome. However, they have the advantage of being learned from a randomly assigned prices and thus can be seen as a source of ground truth to validate our broader estimates.

The mean of the two groups are statistically indistinct and the slope of the red line is not different from one so we cannot reject the null that our estimated elasticities are the true ones.

5.4 Cross Price Elasticities

In this section, we present estimates of average cross-elasticity within our Level 2 categories. A priori it is not obvious if we should expect to primarily find positive or negative cross-price elasticities. Surely price cuts on one product may have competitive impacts
| Level 1 Category | Level 2 Category | Estimated Average Cross-Price Effect | s.e. |
|------------------|------------------|--------------------------------------|------|
| Drinks           | Adult Beverages  | 0.741***                             | 0.246 |
|                  | Water            | 1.041***                             | 0.149 |
|                  | Soft Drinks      | 0.637**                              | 0.257 |
| Protein          | Red Meat         | -0.582***                            | 0.196 |
|                  | Dairy            | 0.018                                | 0.210 |
|                  | Fish             | -0.520*                              | 0.286 |
|                  | Poultry          | -0.429***                            | 0.175 |
| Other Food       | Sugar            | -0.705*                              | 0.382 |
|                  | Sweets           | -0.458                               | 0.397 |
|                  | Veggies          | -1.181**                             | 0.506 |
|                  | Snacks           | -0.847***                            | 0.354 |

Table 2: Cross Price Elasticity, Drinks

on similar products, but loss-leader effect occurs where price cuts on one (for example) dairy product brings in customers who may buy a number of other dairy products. With so many products to consider, precisely quantifying which may serve as such loss leaders is beyond the scope of this paper. Instead, we focus on the aggregate question of which effect predominates in a given product category.

We do this by running a separate specification of Orthogonal Debiased Lasso for the Level 1 categories: Drinks, Protein, and Other Food. Referring back to (5.1), we choose $\Xi_{cp}$ to contain all Level 2 categories and we chose $\Xi_{op}$ to contain all Level 4 categories in order to ensure that we appropriately control for own-price effects.

The results for our cross-price coefficients are presented in Table 2. Interpreting these numbers requires some care. Recall that our cross-price treatments are the average non-self price in any particular set within our hierarchy. As such these numbers can be interpreted to give the expected percentage change in sales of a particular Soft Drinks product, if *every single* other single Soft Drinks product saw a 1% price increase. As such the actual cross-price elasticities between any two products can be calculated by taking the coefficient from Table 2 and dividing it by the number of products in the corresponding Level 2 category.
A Notation

Let $\mathcal{S}^{d-1} = \{ \alpha \in \mathcal{R}^d : \alpha'\alpha = 1 \}$ denote a $d$-dimensional unit sphere. For a matrix $A$, let $\|M\| = \|A\|_2 = \sup_{\alpha \in \mathcal{S}^{d-1}} \|M\alpha\|$. For two sequences of random variables denote $a_n,b_n,n \geq 1 : a_n \preceq_p b_n \equiv a_n = O_P(b_n)$. For two numeric sequences of numbers, denote $a_n,b_n,n \geq 1 : a_n \preceq b_n \equiv a_n = O(b_n)$ . Let $a \wedge b = \min\{a,b\}, a \vee b = \max\{a,b\}$. The $l_2$ norm is denoted by $\|\cdot\|$, the $l_1$ norm is denoted by $\|\cdot\|_1$, the $l_\infty$ is denoted by $\|\cdot\|_\infty$, and the $l_0$ - norm denotes the number of nonzero components of a vector. Given a vector $\delta \in \mathcal{R}^p$ and a set of indices $T \subset \{1,...,p\}$, we denote by $\delta_T$ the vector in $\mathcal{R}^p$ in which $\delta_{T_j} = \delta_j, j \in T$ and $\delta_{T_j} = 0, j \notin T$. The cardinality of $T$ is denoted by $|T|$. Given a covariate vector $x_{it} \in \mathcal{R}^p$, let $x_{it}[T]$ denote the vector $\{x_{it,j}, j \in T\}$. The symbol $\mathbb{E}$ denotes the expectation.

The generic index of an observation in $it, i \in [I] := \{1,2,...,I\}, t \in \{1,2,...,T\}$. The set $I$ consists of pairs $\{(m,c), m \in [M] := \{1,2,...,M\}, c \in [C] := \{1,2,...,C\}\}$, where the first component $m = m(i)$ designates group number, and the second $c \in [C]$ - the cluster index within group. For a random variable $V$, the quantity $v_{m,t}$ denote a $C$-vector $v_{m,t} = [v_{1,t},v_{2,t},...,v_{C,t}]$. For a random $d$-vector $V$, the quantity $v_{m,t}$ denote a $C \times d$-matrix $v_{m,t} = [v'_{1,t},v'_{2,t},...,v'_{C,t}]$. The observations $(Y_{mt},D_{mt},Z_{mt})^{MT}_{m=1}$ are i.i.d across $m \in [M]$. Let $N = MT$ be effective sample size. We will use empirical process notation:

$$\mathbb{E}_N f(x_{it}) \equiv \frac{1}{MT} \sum_{m=1}^{MT} \sum_{c=1}^{C} f(x_{mct}) = \frac{1}{MT} \sum_{it=1}^{IT} f(x_{it})$$

and

$$\mathbb{G}_N f(x_{it}) \equiv \frac{1}{\sqrt{MT}} \sum_{m=1}^{MT} \sum_{c=1}^{C} [f(x_{mct}) - \mathbb{E}f(x_{mct})] = \frac{1}{MT} \sum_{it=1}^{IT} [f(x_{it}) - \mathbb{E}f(x_{it})]$$

Recognize that this differs from regular cross-sectional empirical process notation, since we are not dividing by group size $C$. Let us introduce the covariance matrix of estimated residuals. Let

$$\mathbb{E}_{n,kc} f(x_{it}) := \frac{1}{N} \sum_{(m,t):(g,c,t)\in I_k^c} f(x_{it}) \text{ and } \mathbb{G}_{n,kc} f(x_{it}) := \frac{\sqrt{N}}{N} \sum_{(m,t):(g,c,t)\in I_k^c} [f(x_{it}) - \mathbb{E}f(x_{it})]$$

This operation defines sample average within a partition $I_k$ and observations with index $c$ within their group . This ensures that observations entering the sample average are
i.i.d across groups $m \in [M]$. Let us introduce covariance matrix of estimated residuals

$$
\hat{Q} \equiv \frac{1}{MT} \sum_{it=1}^{IT} \hat{D}_it \hat{D}'_it
$$

and true (oracle) residuals and the maximal entry-wise difference between $\hat{Q}$, $\tilde{Q}$:

$$
\tilde{Q} \equiv \frac{1}{MT} \sum_{it=1}^{IT} \tilde{D}_it \tilde{D}'_it
$$

**B Proofs**

$$
q_N \equiv \max_{1 \leq m,j \leq d} |\tilde{Q} - \hat{Q}|_{m,j}
$$

The following theorem follows from [McLeish, 1974].

**Theorem B.1.** Let $\{\tilde{D}_{mt}, \tilde{U}_{mt}\}_{mt=1}^N$ be a m.d.s. of $d$-vectors. Let Assumption 3.4 and 3.5 hold. Let

$$
Q \equiv E \tilde{D}'_{mt} \tilde{D}_{mt}
$$

and

$$
\Gamma \equiv E \tilde{D}'_{mt} U_{mt} U'mt \tilde{D}_{mt}
$$

and

$$
\Omega \equiv Q^{-1} \Gamma Q^{-1}
$$

and $\Phi(t)$ be a $N(0,1)$ c.d.f. Then, $\forall t \in \mathcal{R}$ and for any $\alpha \in \mathcal{S}^{d-1}$, we have

$$
\lim_{N \to \infty} \frac{\sqrt{N} \alpha' \tilde{D}'_{mt} U_{mt} \| \alpha' \Omega \|^{1/2}}{\sqrt{N} \alpha' Q^{-1} \tilde{D}'_{mt} U_{mt} \| \alpha' \Omega \|^{1/2}} - \Phi(t) = 0. \quad \text{(B.1)}
$$

**Proof.** Let $\xi_{mt} \equiv \frac{\alpha' \tilde{D}'_{mt} U_{mt}}{\sqrt{N} \| \alpha' \Omega \|^{1/2}}$. Let us check conditions of Theorem 3.2 from [McLeish, 1974]:

- (a) $\max_{1 \leq mt \leq N} |\xi_{mt}| = O_P(1)$
- (b) $\mathbb{E} \xi_{mt}^2 1_{\|U_{mt}U'_{mt}\| > \epsilon} \leq \mathbb{E} \|U_{mt}U'_{mt}\| 1_{\|U_{mt}U'_{mt}\| > \epsilon} \to 0, \epsilon \to 0$ by Assumption 3.5
- (c) $\sum_{mt=1}^N \xi_{mt}^2 = \mathbb{E}_N \xi_{mt}^2 \to_p \frac{\alpha' \tilde{D}'_{mt} U_{mt} U'_{mt} \tilde{D}_{mt} Q^{-1} \alpha}{\| \alpha' \Omega \|}$

$\blacksquare$
Proof of Theorem 3.1.

\[ \| \hat{\beta} - \beta_0 \| = \hat{Q}^{-1} \mathbb{E}_N \hat{D}_t \hat{Y}_{it} - \beta_0 \]
\[ \leq \hat{Q}^{-1} \mathbb{E}_N \hat{D}_t \hat{Y}_{it} + \hat{Q}^{-1} \mathbb{E}_N \hat{D}_t \hat{Y}_{it} - \beta_0 \]
\[ \leq \left( \| \hat{Q}^{-1} \mathbb{E}_N \hat{D}_t \hat{Y}_{it} \| + \| \hat{Q}^{-1} \mathbb{E}_N \hat{D}_t \hat{Y}_{it} \| \right) + \| \hat{Q}^{-1} - \hat{Q}^{-1} \| \| \mathbb{E}_N \hat{D}_t \hat{Y}_{it} \| \]
\[ + \| \hat{Q}^{-1} \mathbb{E}_N \hat{D}_t \hat{Y}_{it} - \beta_0 \| \]

Under Assumption 3.3, \( \| \hat{Q} - Q \| \lesssim_p \sqrt{d \log N} \). Therefore, wp \( \to 1 \), all eigenvalues of \( \hat{Q}^{-1} \) are bounded away from zero. Indeed, suppose \( \hat{Q} \) has an eigenvalue less then \( C_{\min}/2 \).

Therefore, w.h.p. the eigenvalues of \( \hat{Q} \) are bounded away from zero. By Lemma D.1 \( \| \hat{Q} - Q \| \lesssim_p d \mathbf{m}_N^2 \). Therefore, w.h.p. the eigenvalues of \( \hat{Q} \) are bounded away from zero. By Lemma D.1

\[ \| a \| \lesssim_p [\sqrt{d} \mathbf{m}_N 1_N + d \mathbf{m}_N^2 \| \beta_0 \| + \lambda_N] \]
\[ \| b \| \| \mathbb{E}_N \hat{D}_t \hat{Y}_{it} \| \lesssim_p \| \hat{Q}^{-1} - \hat{Q}^{-1} \| (\| \mathbb{E}_N \| \beta_0 \| ) + O_p(1/N) \]
\[ \lesssim_p \| \hat{Q}^{-1} - \hat{Q}^{-1} \| \| \hat{Q} - Q \| \| \hat{Q}^{-1} \| \]
\[ \lesssim_p [d \mathbf{m}_N^2 + \sqrt{d} \lambda_N] \| \beta_0 \| \]
\[ \| c \| \lesssim_p \sqrt{d/N} \]
\[ \| \hat{\beta} - \beta_0 \| \lesssim_p \sqrt{d} \mathbf{m}_N 1_N \lor (d \mathbf{m}_N^2 + \sqrt{d} \lambda_N) \| \beta_0 \| \lor \sqrt{d/N} \quad (B.2) \]

Step 2: Asymptotic Linearity

Let

\[ \hat{Y}_{it} = \hat{D}_t \beta_0 + R_{it} + U_{it} \]

where

\[ R_{it} = (\hat{d}_i(Z_{it}) - d_i(Z_{it}))' \beta_0 + (l_i(Z_{it}) - \hat{l}_i(Z_{it})), i \in \{1, 2, ..., N \} \]

summarizes first stage approximation error.
\[ \sqrt{N} \alpha'(\hat{\beta} - \beta) = \sqrt{N} \alpha'(\hat{Q}^{-1}E_N \hat{D}_{it} \hat{Y}_{it} - \beta_0) \]  
\[ = \sqrt{N} \alpha' \hat{Q}^{-1}E_N \hat{D}_{it}(R_{it} + U_{it}) \]  
\[ = \sqrt{N} \alpha' Q^{-1} E_N \hat{D}_{it} U_{it} + R_{1,N}(\alpha) \]  

where \[ R_{1,N}(\alpha) = \sqrt{N} \alpha' Q^{-1} [E_N \hat{D}_{it} (R_{it} + U_{it}) - E_N \hat{D}_{it} U_{it}] + \sqrt{N} \alpha'(\hat{Q}^{-1} - Q^{-1})E_N \hat{D}_{it} U_{it} \]

In Step 1 it was shown that the eigenvalues of \( \hat{Q}^{-1} \) are bounded away from zero. By Lemma \[ D.1 \]

\[ |S_1| \leq \| \alpha \| \| \hat{Q}^{-1} \| \sqrt{N} [E_N \hat{D}_{it} (R_{it} + U_{it}) - E_N \hat{D}_{it} U_{it}] \| \lesssim \sqrt{N} [\sqrt{d}m_N 1_N + d m_N^2 \| \beta_0 \| + \lambda_N] \]

By Lemma \[ D.1 \]

\[ |S_2| \leq \| \alpha \| \| \hat{Q}^{-1} \| \sqrt{N} [E_N \hat{D}_{it} U_{it}] \| \lesssim \sqrt{N} [\sqrt{d}m_N 1_N + d m_N^2 \| \beta_0 \| + \lambda_N] \]

Equation \[ B.5 \] establishes Asymptotic Linearity representation of \( \hat{\beta} \). Theorem \[ B.1 \] implies Asymptotic Normality of \( \hat{\beta} \) with asymptotic variance

\[ \Omega = Q^{-1} E \hat{D}_{mt} U_{mt} U_{mt}' \hat{D}_{mt} Q^{-1} \]

**Step 3: Asymptotic Variance** Let \( \hat{U}_{mt} = \hat{Y}_{it} - \hat{D}_{mt} \hat{\beta} \) be estimated outcome disturbances. Then, asymptotic variance \( \Omega = Q^{-1} \Gamma Q^{-1} \) can be consistently estimated by \( \Omega = \hat{Q}^{-1} \hat{\Gamma} \hat{Q}^{-1} \) where

\[ \hat{\Gamma} = E_{MT} \hat{D}_{mt} \hat{U}_{mt} \hat{U}_{mt}' \hat{D}_{mt} \]

Let \( \tilde{\Gamma} = E_{MT} \hat{D}_{mt} U_{mt} U_{mt}' \hat{D}_{mt} \) be a oracle estimate of \( \Gamma \), where oracle knows \( \beta_0 \) and the first stage estimates. Let \( \xi_{it} := \hat{D}_{it}' U_{it} \) and \( \tilde{\xi}_{it} := \hat{D}_{it}' \hat{U}_{it} \) be \( d \)-vectors. Recognize that
\[ \hat{\Gamma} = \mathbb{E}_N \hat{\xi}_{it} \hat{\xi}_{it} \] and \[ \bar{\Gamma} = \mathbb{E}_N \xi_{it} \xi_{it} \]. Recognize that

\[
\| \hat{\Gamma} - \bar{\Gamma} \| = \| \mathbb{E}_M (\hat{\xi}_{it} - \xi_{it}) \| + \| \mathbb{E}_M (\xi_{it} - \hat{\xi}_{it}) \|
\leq \| \mathbb{E}_M (\hat{\xi}_{it} - \xi_{it}) \|^2 \sup_{\alpha \in \mathcal{S}^{d-1}} (\mathbb{E}_M (\alpha^\top \hat{\xi}_{it}^2))^{1/2}
+ \| \mathbb{E}_M (\xi_{it} - \hat{\xi}_{it}) \|^2 \sup_{\alpha \in \mathcal{S}^{d-1}} (\mathbb{E}_M (\alpha^\top \xi_{it}^2))^{1/2}
\lesssim_P aO_P(1)
\]

Recognize that both \( \hat{\xi}_{it} \) and \( \xi_{it} \) are inner products of \( C \) summands.

\[
\hat{\xi}_{it} - \xi_{it} = \sum_{c=1}^C \hat{D}_{it}[\hat{Y}_{it} - \hat{D}_{it}^\top \beta_0 + \hat{D}_{it}^\top \hat{\beta} - \hat{D}_{it}^\top \hat{\beta}]
- \sum_{c=1}^C \hat{D}_{it} U_{it}
\]

\[
a = \| \mathbb{E}_M (\hat{\xi}_{it} - \xi_{it})^2 \| \leq C \| \mathbb{E}_N [\hat{D}_{it}[\hat{Y}_{it} - \hat{D}_{it}^\top \beta_0 + \hat{D}_{it}^\top \hat{\beta} - \hat{D}_{it}^\top \hat{\beta}]
- \sum_{c=1}^C \hat{D}_{it} U_{it}]^2 \|
\lesssim_P \| \mathbb{E}_N [\hat{D}_{it}[R_{it} + U_{it}] - \hat{D}_{it}[U_{it}]]^2 \| + \| \hat{\beta} - \beta_0 \|^2 = o_P(1)
\]

By Lemma [D.1] \( \| \hat{Q} - Q \| \lesssim_P d m_N^2 + \sqrt{d} \lambda_N = o_P(1) \). By Assumption 3.3 \( \| \hat{Q} - Q \| = o_P(1) \).

\[
\hat{\Omega} = Q^{-1} \hat{\Gamma} Q^{-1} = (Q^{-1} + o_P(1))(\Gamma + o_P(1))(Q^{-1} + o_P(1))
\]

\[ \textbf{Proof of Theorem 3.2}. \] For every \( \delta = \hat{\beta} - \beta_0, \delta \in \mathbb{R}^d \) we use the notation:

\[
\| \delta \|_{2,N} = (\mathbb{E}_N (\hat{D}_{it}^\top \delta)^2)^{1/2}
\]

and

\[
\| \delta \|_{d2,N} = (\mathbb{E}_N (\hat{D}_{it}^\top \delta)^2)^{1/2}
\]
\[ \hat{Q}(\beta_L) - \hat{Q}(\beta_0) - \mathbb{E}_N(\hat{D}_{it}\delta) = -2\mathbb{E}_N[U_{it}\hat{D}_{it}\delta] \]  
(B.6)

\[ -2\mathbb{E}_N[U_{it}(d_{i0}(Z_{it}) - \hat{d}_i(Z_{it}))']\delta] \]  
(B.7)

\[ -2\mathbb{E}_N[(l_{i0}(Z_{it}) - \hat{l}_i(Z_{it})) + (d_{i0}(Z_{it}) - \hat{d}_i(Z_{it}))'\beta_0(\hat{D}_{it})']\delta] \]  
(B.8)

\[ -2\mathbb{E}_N[(l_{i0}(Z_{it}) - \hat{l}_i(Z_{it})) + (d_{i0}(Z_{it}) - \hat{d}_i(Z_{it}))'\beta_0(d_{i0}(Z_{it}) - \hat{d}_i(Z_{it}))']\delta] \]  
(B.9)

By Lemma D.4, \(|b + c| \lesssim_P D^2\sqrt{\frac{\log(2\beta)}{N}} + m_N^2s\|\beta_0\|^2 + m_N^01_N\). Since \(a\) is a sample average of bounded martingale difference sequences \(a \lesssim_P \lambda_N + m_N^2s\|\beta_0\|^2 + m_N^01_N\). Therefore, with high probability \(\exists c > 1 \ \lambda \geq c\sqrt{\frac{\log\beta}{N}} + \sqrt{\frac{\log(2\beta)}{N}} + m_N^2s\|\beta_0\|^2 + m_N^01_N + \lambda_N\). Optimality of \(\hat{\beta}_L\) and the choice of \(\lambda\) imply:

\[ \lambda(||\beta_0||_1 - ||\hat{\beta}||_1) \geq ||\delta||^2_{d,2,1} \geq -\lambda/c\|\delta\|_1 \]  
(B.10)

Triangle inequality implies:

\[ \frac{-\lambda/c\|\delta\|_1 \leq \lambda(||\beta_0||_1 - ||\hat{\beta}||_1) \leq \lambda(||\delta_T||_1 - ||\delta_{T'}||_1)}{\|\delta_{T'}\|_1 \leq \frac{c + 1}{c - 1}\|\delta_T\|_1} \]

Therefore, \(\delta\) belongs to the restricted set in the \(\mathcal{RE}(\bar{c})\), where \(\bar{c} = \frac{c + 1}{c - 1}\). By Lemma D.3

\[ \delta \in \mathcal{RE}(\bar{c}) \Rightarrow \]

\[ (1 - \frac{(1 + \bar{c})^2}{\kappa(Q,T,\bar{c})^2})\|\delta\|^2_{d,2,1} \leq \|\delta\|^2_{d,2,1} \leq \|\delta\|^2_{d,2,1} \frac{\kappa(Q,T,\bar{c})^2}{(1 - q_N(1 + \bar{c})^2s/\kappa(Q,T,\bar{c})^2)} \]

\[ \|\delta\|^2_{d,2,1} \leq \frac{\|\delta\|^2_{d,2,1}}{(1 - q_N(1 + \bar{c})^2s/\kappa(Q,T,\bar{c})^2)} \]

\[ \|\delta\|^2_{d,2,1} \leq \frac{1}{\lambda\|\delta_T\|_1(1 - q_N(1 + \bar{c})^2s/\kappa(Q,T,\bar{c})^2)} \]

\[ \|\delta\|^2_{d,2,1} \leq \frac{1}{\kappa(Q,T,\bar{c})(1 - q_N(1 + \bar{c})^2s/\kappa(Q,T,\bar{c})^2)} \]
\[ \|\delta\|_1 \leq \|\delta\|_{2,N} \frac{\sqrt{s}}{\kappa(Q,T,2\bar{c})} \leq \lambda \frac{s}{\kappa(Q,T,2\bar{c})\kappa(Q,T,c)} \frac{1}{(1-q_N(1+\bar{c})^2s/\kappa(Q,T,c)^2)} \]

\section{Inference in High-Dimensional Sparse Models}

\textbf{Definition C.1} (Orthogonalization matrix). Let \( \mu_N : N \geq 1 \) be an \( o(1) \) sequence. We say that a \( d \times d \)-dimensional matrix \( M = [m_1, \ldots, m_d]^\top \) orthogonalizes a given matrix \( Q \) at rate \( \mu_N \) if:

\[ \|MQ - I\|_\infty \leq \mu_N \]  

(C.1)

Denote by \( M_{\mu_N}(Q) \) the set of all matrices that orthogonalize \( Q \) at rate \( \mu_N \). We will refer to it as orthogonalization set of \( M \).

\textbf{Lemma C.1} (Relation between orthogonalization sets of true and estimated residuals). Let \( \hat{Q} \) and \( \tilde{Q} \) be a sample covariance matrix of estimated and true residuals. Let and \( M_{\mu_N} (\hat{Q}), M_{\mu_N} (\tilde{Q}) \) be their respective orthogonalization sets with common rate \( \mu_N \). Then, \( \forall M \in M_{\mu_N} (\tilde{Q}) \) that satisfy Assumption 3.8, with high probability

\[ P(M \in M(\hat{Q})) \to 1, N \to \infty, d \to \infty \]

Moreover, since \( Q^{-1} \in M(\tilde{Q}) \) by Lemma 6.2 of [Javanmard and Montanari, 2014], \( Q^{-1} \in M(\hat{Q}) \). Therefore, \( M(\hat{Q}) \) is non-empty w.h.p.

\textbf{Lemma C.2} (Asymptotic Linearity of \( \hat{\beta}_{DOL} \) and \( \hat{\beta}_{Ridge} \)).

\[ \sqrt{N}(\hat{\beta}_{DOL} - \beta_0) = \sqrt{N}M\mathbb{E}_N \hat{D}_it(\tilde{Y}_{it} - \hat{D}_it\hat{\beta}_L) + \hat{\beta}_L - \beta_0 \]  

(C.2)

where \( \|R_{1,N}\|_\infty \leq P \sqrt{N}\lambda\mu_N \vee \sqrt{N}[\sqrt{s}m_N + l_N](m_Nm_0 \vee \lambda_N)|T| \)

\textbf{Proof of Lemma C.1.}

\[ |Q^{-1}\hat{Q} - I|_\infty \leq |Q^{-1}\hat{Q} - I|_\infty + |Q^{-1}(\hat{Q} - \tilde{Q})|_\infty \]
\[ |Q^{-1}(\tilde{Q} - \hat{Q})|_\infty \leq \max_{1 \leq m,j \leq d} |Q^{-1}_{j,m} (\tilde{Q} - \hat{Q})|_m \]
\[ \leq \max_{1 \leq j \leq d} \sum_{i=1}^d |Q^{-1}|_{j,i} \max_{1 \leq m,j \leq d} |(\tilde{Q} - \hat{Q})_{i,m}| \]
\[ \lesssim m0qN \]

where the last inequality follows from Assumption 3.8 and Lemma D.2. By Lemma 6.2 of [Javanmard and Montanari, 2014],
\[ \Pr(|Q^{-1}\tilde{Q} - I|_\infty \geq a\sqrt{\frac{\log d}{N}}) \leq 2d^{-c_2} \quad (C.3) \]
which finishes the proof.

\[ \blacksquare \]

**Proof of Lemma C.2.** Let
\[ R_{it} = (d_{i,0}(Z_{it}) - \tilde{d}_i(Z_{it}))'\beta_0 + (\tilde{l}(Z_{it}) - l_{i0}(Z_{it})), \quad i \in \{1, 2, \ldots, N\} \quad (C.4) \]
summarize the first-stage approximation error, that contaminates the outcome. Assumption 3.1 implies a rate on the bias of \( R_{it} \)
\[ (\mathbb{E}[(d_{i,0}(Z_{it}) - d(Z_{it}))'\beta_0 + (l(Z_{it}) - l_{i0}(Z_{it}))]^2)^{1/2} \leq \sqrt{5mN} \vee 1_N \]
\[ \tilde{Y}_{it} - \tilde{D}_{it} \beta_0 = \tilde{Y}_{it} - \tilde{D}_{it} \beta_0 + (\tilde{Y}_{it} - \tilde{Y}_{it}) - (\tilde{D}_{it} - \tilde{D}_{it}) \beta_0 \]
\[ = U_{it} + R_{it} \]
and
\[ \tilde{Y}_{it} - \tilde{D}_{it} \beta_L = U_{it} + R_{it} + (\tilde{D}_{it})'(\beta_0 - \beta_L) \]
\[ \tilde{\beta}_{DOL} = M\mathbb{E}_N [\tilde{D}_{it}'](\tilde{Y}_{it} - \tilde{D}_{it} \beta_L) + \beta_L \]
\[ = M\mathbb{E}_N [\tilde{D}_{it} + [\tilde{D}_{it} - \tilde{D}_{it}]'](U_{it} + R_{it} + \tilde{D}_{it}(\beta_0 - \beta_L) + \beta_L \]
\[ = \beta_0 + M\mathbb{E}_N \tilde{D}_{it}'U_{it} + \Delta_U + \Delta_D + \Delta_R + \Delta \]

42
\[ \Delta_U = ME_N[\hat{D}_{it} - \hat{D}_{it}]'U_{it} = M \sum_{k=1}^{K} \sum_{c=1}^{C} E_{n, kc} \Delta_U, kc \]

\[ \Delta_D = ME_N[\hat{D}_{it} - \hat{D}_{it}]'R_{it} = M \sum_{k=1}^{K} \sum_{c=1}^{C} E_{n, kc} \Delta_D, kc \]

\[ \Delta_R = ME_N\hat{D}_it'R_{it} = M \sum_{k=1}^{K} \sum_{c=1}^{C} E_{n, kc} \Delta_R, kc \]

\[ \Delta = (M\hat{Q} - I)(\beta_0 - \hat{\beta}_L) \]

### C.0.1 Step 1

Let \( m_j^0 \) be the row of a sparse approximation of \( Q^{-1} \) and let \( T := \{k, (m_j^0)_k \neq 0\} \) be the set of its active coordinates: \(|T| = O(1)\). Let \( \delta = m_j - m_j^0 \). Since \( Q^{-1} \in M_{\mu N}(\hat{Q}) \), triangular inequality implies:

\[ \|m_j\|_1 \leq \|(m_j^0)_T\|_1 \leq \|(m_j)_T\|_1 + \|\delta_T\|_1 \]

\[ \|(m_j)_T\|_1 + \|(m_j)_T^c\|_1 \leq \|(m_j)_T\|_1 + \|\delta_T\|_1 \]

\[ \|\delta_T^c\|_1 = \|(m_j)_T^c\|_1 \leq \|\delta_T\|_1 \]

Therefore, \( \delta \in R\mathcal{E}(2) \), that is \( \|\delta\|_1 \leq 2\|\delta_T\|_1 \).

### C.0.2 Step 2: Covariance of Approximation Errors \( \Delta_{D, kc} \)

For any vector \( m_j = m_j^0 + \delta, m_j \in \mathcal{R}^d \),

\[ \frac{(m_j')(\hat{d}_i(Z_{it}) - d_{i,0}(Z_{it}))}{(a+b)^2} \leq 2 \left[ \frac{((m_j^0)'(\hat{d}_i(Z_{it}) - d_{i,0}(Z_{it}))}{a^2} + \frac{(\delta')(\hat{d}_i(Z_{it}) - d_{i,0}(Z_{it}))}{b^2} \right] \]

Applying \( E_{n, kc}(\cdot) \) to both sides of inequality:

\[ E_{n, kc}(m_j'(\hat{d}_i(Z_{it}) - d_{i,0}(Z_{it}))) \leq 2[E_{n, kc}(m_j^0)'(\hat{d}_i(Z_{it}) - d_{i,0}(Z_{it}))] + 2[E_{n, kc}(\delta')(\hat{d}_i(Z_{it}) - d_{i,0}(Z_{it}))] \]

43
Let $\Gamma := \mathbb{E}_N(\tilde{d}_i(Z_{it}) - d_{i,0}(Z_{it}))(\tilde{d}_i(Z_{it}) - d_{i,0}(Z_{it}))'$. 

$$
\mathbb{E}_{n,kc}(\delta'(\tilde{d}_i(Z_{it}) - d_{i,0}(Z_{it})))^2 = \delta'\Gamma\delta \leq \max_{1 \leq j,k \leq d} |\Gamma|_{j,k}\|\delta\|_1^2
$$

$$
\leq i) q_N\|\delta\|_1^2
$$

$$
\leq iii) q_N4\|\delta\|_T^2
$$

$$
= iv) O_P(4q_N|T|) = O_P(4[\lambda_N + m^2_N]|T|) \quad (C.5)
$$

where (ii) is by Lemma D.2, (iii) is by $\delta \in \mathcal{RE}(2)$ (Step 1), and (iv) is by $T$ is finite.

Assumption 3.2 implies:

$$
\mathbb{E}_N(m^0_j)'(\tilde{d}_i(Z_{it}) - d_{i,0}(Z_{it})))^2 \leq m_0[\lambda_N + m^2_N]
$$

we obtain a bound for any $j \in \{1, 2, \ldots, d\}$:

$$
\sqrt{N}|\Delta_{D,kc}| = \sqrt{N}\mathbb{E}_{n,kc}[m^j_i(\tilde{d}_i(Z_{it}) - d_{i,0}(Z_{it}))]U_{it}|
$$

$$
\leq \sqrt{N}((\mathbb{E}_{n,kc}m^j_i(\tilde{d}_i(Z_{it}) - d_{i,0}(Z_{it})))^2)^{1/2}(\mathbb{E}_{n,kc}R_{it}^2)^{1/2}
$$

$$
\leq p (\sqrt{N}\mathbf{m}_N m_0 \lor \lambda_N |T|)(\sqrt{N}\mathbf{m}_N \lor 1_N \lor \lambda_N)
$$

C.0.3 Step 3: Covariance of Approximation Error and Sampling Error $\Delta_{U,kc}$

Recall that $\Delta_{U,kc} = \mathbb{E}_{n,kc}[m^j_i(\tilde{d}_i(Z_{it}) - d_{i,0}(Z_{it}))]U_{it}$. Since $U_{it}[(D_{it}, Z_{it})_{it=1}^N] = 0$, $\Delta_{U,kc}$ is mean zero.

$$
\mathbb{E}[\mathbb{E}_{n,kc}[m^j_i(\tilde{d}_i(Z_{it}) - d_{i,0}(Z_{it})]U_{it}[(D_{it}, Z_{it})_{it=1}^N] = 0
$$

$$
\sqrt{N}|\Delta_{U,kc}| \leq p [\mathbb{E}[\mathbb{E}_{n,kc}[m^j_i(\tilde{d}_i(Z_{it}) - d_{i,0}(Z_{it}))(U_{it})^2)]^{1/2}
$$

$$
\leq iv) 4q_N m_0 \bar{\sigma}
$$

where $i$ is by Markov inequality conditionally on $(D_{it}, Z_{it})_{it=1}^N$, $ii$ is by uncorrelatedness of $(U_{it})_{it=1}^N$ and $iii$ is by Step 2 (Equation C.5).
C.0.4 Step 4: $\Delta_{R,kc}$

Fix a partition $k \in [K]$. Conditionally on $I^c_k$,

$$\mathbb{E}[\sqrt{n} \mathbb{E}_{n,kc}(m_j^0)' \tilde{D}_{it} R_{it} | I^c_k] = 0$$

$$\langle \sqrt{N} | \Delta_{R,kc} \rangle^2 \lesssim_P n \mathbb{E}[\mathbb{E}_{n,kc}(m_j^0)' \tilde{D}_{it} R_{it} | I^c_k]^2 \quad \leq \quad \mathbb{E}[(m_j^0)' \tilde{D}_{it} R_{it}]^2$$

$$\lesssim^{ii} m_0 \mathbb{E}[|| \tilde{D}_{it} ||^2 | I^c_k, Z_{it}] \mathbb{E}_{n,kc} R_{it}^2$$

$$\lesssim^{iii} m_0^2 (sdm_N^2 + 1^2 + \lambda_N)$$

where $i$ by Markov conditionally on $I^c_k$, $(Z_{it})_{it=1}^N$ and $iii$ is by Equation \ref{eq:4}.

$$\mathbb{E} [ \mathbb{E}_{n,kc} \tilde{D}_{it} R_{it} | I^c_k] = \mathbb{E}_{n,kc} [\mathbb{E} [ D_{it} | I^c_k, Z_{it}] R_{it} | I^c_k] = 0$$

Azouna-Hoeffding inequality implies

$$\max_{1 \leq j \leq d} | \mathbb{E}_{n,kc} \tilde{D}_{j,it} R_{it} || I^c_k \lesssim_P \sqrt{\frac{\log d}{N}}$$

$$\sqrt{N} | \delta^c \mathbb{E}_{n,kc} \tilde{D}_{j,it} R_{it} | \leq \sqrt{N} || \delta ||_1 \max_{1 \leq j \leq d} | \mathbb{E}_{n,kc} \tilde{D}_{j,it} R_{it} |$$

$$\leq \sqrt{N} || \delta ||_1 D \sqrt{\frac{s \log d}{N}}$$

$$\leq \sqrt{N} 2 |T| \sqrt{\frac{\log d}{N}} D \sqrt{\frac{s \log d}{N}}$$

Therefore, $\sqrt{N} | \Delta_{R,kc} | = o_P(1)$

C.0.5 Step 4: $\Delta$

$$\sqrt{N} || \Delta ||_\infty \leq || M \hat{Q} - I ||_\infty || \beta_0 - \hat{\beta}_L ||_1$$

$$\lesssim_P 2 \sqrt{N} \mu_N \lambda s$$
C.0.6 Consistency of $\hat{\Omega}$

Let $\hat{U}_{mt} = \hat{Y}_{mt} - \hat{D}_{mt}\hat{\beta}_L$ be estimated outcome disturbances. Then, asymptotic variance $\Omega = MTM'$ can be consistently estimated by

$$\hat{\Omega} = M\hat{\Gamma}'\hat{U}_{mt}\hat{U}_{mt}'\hat{D}_{mt}M'$$

Let $\xi_{it} := \hat{D}'_{it}U_{it}$ and $\hat{\xi}_{it} := \hat{D}'_{it}\hat{U}_{it}$ be $d$-vectors. Recognize that $\hat{\Gamma} = E_N\hat{\xi}_{it}\hat{\xi}'_{it}$ and $\tilde{\Gamma} = E_N\xi_{it}\xi'_it$. Let $m_j$ be the $j$'th row of $M$. Recognize that:

$$m_j'\hat{\Gamma} - \tilde{\Gamma}m_j = E_Mtm_j'\hat{\xi}_{it}\hat{\xi}'_{it} - \xi_{it}\xi'_itm_j$$

$$\leq E_Mtm_j'\hat{\xi}_{it}\hat{\xi}'_{it}m_j + E_Mtm_j'\hat{\xi}_{it}\xi'_itm_j$$

$$\leq (E_Mtm_j'\hat{\xi}_{it}\hat{\xi}'_{it})^{1/2}(E_Mtm_j'\hat{\xi}_{it})^{1/2}$$

$$+ (E_Mtm_j'\hat{\xi}_{it}\xi'_it)^{1/2}(E_Mtm_j'\xi_{it})^{1/2}$$

$$\lesssim_P aO_P(1)$$

Proof: Recognize that both $\hat{\xi}_{it}$ and $\xi_{it}$ are inner products of $C$ summands.

$$\hat{\xi}_{it} - \xi_{it} = \left[\sum_{c=1}^{C} \hat{D}_c[R_{it} - \hat{D}'_{ct}\hat{\beta}_0 + \hat{D}'_{ct}\beta_0 - \hat{D}'_{ct}\hat{\beta}_L] - \sum_{c=1}^{C} \hat{D}_cU_{it}\right]$$

$$a = E_Mtm_j'\hat{\xi}_{it}\xi'_it$$

$$\leq C\left[E_Nm_j'\hat{D}_c[R_{it} - \hat{D}'_{ct}\hat{\beta}_0 + \hat{D}'_{ct}\beta_0 - \hat{D}'_{ct}\hat{\beta}_L] - \sum_{c=1}^{C} m_j'\hat{D}_cU_{it}\right]^2$$

$$\lesssim_P \|E_N(m_j'\hat{D}_c[R_{it} - \hat{D}_cU_{it}])^2\|_{o_P(1)}$$

$$+ m_0 \max_{1 \leq k, j \leq d} \|\hat{Q}_{kj}\|_{\beta_L - \beta_0}^2 = o_P(1)$$

46
D Supplementary Lemmas

Lemma D.1 (First Stage Error).
\[
\|\hat{Q} - \tilde{Q}\|_2 \lesssim_P d m_N^2 + \sqrt{d} \lambda_N \\
\sqrt{N} \|E_N[\tilde{D}_{i,t}[R_{i,t} + U_{i,t}]]\|_2 \lesssim_P \sqrt{N} \sqrt{d} m_N l_N + d m_N^2 \|\beta_0\| + \sqrt{N} \lambda_N \\
\|E_N[\tilde{D}_{i,t}[R_{i,t} + U_{i,t}]]^2\|_2 \lesssim_P d^2 m_N^2 \|\beta_0\|^2 + d l_N^2
\]

Lemma D.2 (Bound on Restricted Eigenvalue of Treatment Residuals). Let
\[
q_N = \max_{1 \leq m,j \leq d} \|E_N[\hat{Q} - \tilde{Q}]_{m,j}\| \\
q_N \leq m_N^2
\]

Lemma D.3 (In-Sample Prediction Norm: True and Estimated Residuals). Let \(\bar{c} > 1\) be a constant. Let \(\delta \in \mathbb{R}^p\) belong to the set \(\mathcal{RE}(\bar{c})\)
\[
\|\delta_T\|_1 \leq \bar{c} \|\delta_T\|_1
\]
and assume \(3.7(\bar{c})\) holds. Let \(q_N\) be defined in Lemma D.2. If \(q_N \frac{(1+\bar{c})^2 s}{\kappa(Q,T,\bar{c})} < 1\),
\[
\sqrt{1-q_N \frac{(1+\bar{c})^2 s}{\kappa(Q,T,\bar{c})}} \leq \|\delta\|_{2,N} \leq \sqrt{1+q_N \frac{(1+\bar{c})^2 s}{\kappa(Q,T,\bar{c})}}
\]
(\ref{eq:D.1})

Lemma D.4 (Maximal Inequality for First Stage Approximation Errors). Let \(\tilde{d}_i(Z_{it}), \tilde{l}_i(Z_{it})\) be the first-stage estimate of the treatment and outcome reduced form, and \(U_{it}\) is the sampling error. Then, the following bounds hold w.h.p:
\[
\max_{1 \leq m \leq d} \mathbb{E}_N\|\tilde{d}_{m,0}(Z_{it}) - d_{m,0}(Z_{it})\|_1 \leq (\lambda_N + m_N l_N) \quad (D.2) \\
\max_{1 \leq m \leq d} \mathbb{E}_N\|(\tilde{d}_{m,0}(Z_{it}) - d_{m,0}(Z_{it}))'(\tilde{l}_i(Z_{it}) - l(Z_{it}))'\beta_0\| \leq (\lambda_N + m_N^2 s \|\beta_0\|^2) \quad (D.3)
\]
In addition, by Azouma-Hoeffding inequality

\[
\max_{1 \leq m \leq d} \mathbb{E}_N \| \tilde{D}_{i,m}(\hat{l}_i(Z_{it}) - l(Z_{it})) \| \leq (DL \sqrt{\frac{\log(2d)}{N}}) \quad \text{(D.4)}
\]

\[
\max_{1 \leq m \leq d} \mathbb{E}_N \| \tilde{D}_{i,m}(\hat{d}_i(Z_{it}) - d(Z_{it}))' \beta_0 \| \leq (D^2 \sqrt{\frac{\log(2d)}{N}}) \quad \text{(D.5)}
\]

and

\[
\max_{1 \leq m \leq d} \| \mathbb{E}_N (\hat{d}_{m,0}(Z_{it}) - d_{m,0}(Z_{it})) U_{it} \| \leq (D^2 \sigma^2 \sqrt{\frac{\log 2d}{N}})
\]

E Proofs for Section D

The Proofs of Lemmas D.1, D.1, D.2 in cross-sectional case follow the steps below:

1. Decompose a term into \( KC \) summands, corresponding to \( K \) partitions and \( C \) clusters. Within each cluster \( \tilde{D}_{it}, \hat{Y}_{it} \) are m.d.s.

2. Equate the first-order bias to zero by orthogonality and conditional independence

3. Bound the first-order term by Markov inequality and conditional independence

4. Bound the second-order out-of-sample error by Assumption 3.2

Proof of Lemma D.1

Step 1

\[
\hat{Q} - \tilde{Q} = \mathbb{E}_N (\tilde{D}_{it}) (d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))' + \mathbb{E}_N (\tilde{D}_{it}) (d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))' + \mathbb{E}_N (d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it})) (d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))'
\]

Let

\[
\mathbb{E}_{n,kc} f(x_{it}) := \frac{1}{N} \sum_{(m,t):(m,c,t) \in I_k^c} f(x_{it}) \quad \text{and} \quad G_{n,kc} f(x_{it}) := \frac{1}{\sqrt{N}} \sum_{(m,t):(m,c,t) \in I_k^c} [f(x_{it}) - \mathbb{E} f(x_{it})]
\]

The summation in each \( a_{kc}, b_{kc} \) is by i.i.d groups \( m \in [M] \) and time \( t \in [T] \).
\[ a = E_N(\hat{D}_{it}(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it})))' = \frac{1}{KC} \sum_{k=1}^{K} \sum_{c=1}^{C} E_{n,kc}(\hat{D}_{it}(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it})))'_{a_{kc}} \]

\[ b = E_N(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it})))' \]

\[ = \frac{1}{KC} \sum_{k=1}^{K} \sum_{c=1}^{C} E_{n,kc}(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it})))'_{b_{kc}} \]  

(E.1)

**Step 2**

\[ E[a_{kc} | (W_{it})_{i \in I_k}^c] = E_{n,kc}E(Z_{it})E[\hat{D}_{it} | Z_{it}, (W_{it})_{i \in I_k}^c](\hat{d}_i(Z_{it}) - d(Z_{it})) \]  

\[ E[\hat{D}_{it} | Z_{it}] = 0 \]

**Step 3**

\[ E[||\alpha' a_{kc}||^2 | (W_{it})_{i \in I_k}^c] = E[||\alpha' E_{n,kc}(\hat{D}_{it})(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))||^2 | (W_{it})_{i \in I_k}^c] \]

\[ = \frac{1}{n} E[||\alpha' (\hat{D}_{it})(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))||^2 | (W_{it})_{i \in I_k}^c] \]

\[ = \frac{1}{n} E[Z_{it}E[|\alpha' \hat{D}_{it}^2 | Z_{it}, (W_{it})_{i \in I_k}^c]| |d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it})||^2 | (W_{it})_{i \in I_k}^c] \]

\[ \leq n^{-1} C_{\max} d m^2_N \]

where equality \( i \) follows from conditional exogeneity of errors \( \hat{D}_{it} \) across \((m, t) \in [G, T]\). Markov inequality implies:

\[ ||a|| \leq \sum_{k=1}^{K} ||a_{kc}|| \leq \sum_{k=1}^{K} \sup_{\alpha \in \mathbb{R}^k: ||\alpha||=1} ||\alpha' a_{kc}|| = O_P(\sqrt{dm}N/\sqrt{N}) \]

**Step 4**

The bias of \( b_{kc} \) attains the following bound:

\[ ||E[\alpha' b_{kc} | (W_{it})_{i \in I_k}^c]||^2 = \sum_{j=1}^{d} \left( E(\alpha'(d_i(Z_{it}) - d_{i,0}(Z_{it}))) (\hat{d}_i(Z_{it}) - d_{i,0}(Z_{it}))^2 \right) \]

\[ \leq \sum_{j=1}^{d} \left( E(\hat{d}_i(Z_{it}) - d_{i,0}(Z_{it}))^2 E(\alpha'(d_i(Z_{it}) - d_{i,0}(Z_{it})))^2 \right) \]

\[ \leq (dm^2_N)^2 \]

Under Assumption 3.2
\[ \|\alpha'(b_{kc} - \mathbb{E}[b_{kc}|(W_{it})_{i \in I_k^c}])(W_{it})_{i \in I_k^c} \| \lesssim \sqrt{d} \lambda_N \]

In case \( T = 1 \) (no time dependence), the Step 4(b) can be shown as follows.

Conditional variance of \( b_{kc} \) attains the following bound:

\[
\mathbb{E}[\|\alpha'(b_{kc} - \mathbb{E}[b_{kc}|(W_{it})_{i \in I_k^c}])(W_{it})_{i \in I_k^c} \|^2 |(W_{it})_{i \in I_k^c}] \lesssim d/\sqrt{N}
\]

Therefore, \( \lambda_N := \sqrt{1/N} \) in Assumption 3.2.

\[
\|\hat{Q} - \hat{Q}\| = \|a + a' + b\| \lesssim \sqrt{d} \lambda_N + \sqrt{d} \lambda_N
\]

Step 1

\[
[\mathbb{E}_N[\hat{D}_{it}(R_{it} + U_{it}) - \hat{D}_{it}\hat{U}_{it}]] = \mathbb{E}_N(\tilde{d}_i(Z_{it}) - \bar{d}_i(Z_{it}))U_{it}
\]

\[
+ \mathbb{E}_N(\tilde{d}_i(Z_{it}) - \bar{d}_i(Z_{it}))R_{it}
\]

\[
+ \mathbb{E}_N \tilde{D}_{it}R_{it}
\]

Let

\[
\mathbb{E}_{n,kc}f(x_{it}) := \frac{1}{N} \sum_{(m,t):(g,c,t) \in I_k^c} f(x_{it}) \quad \text{and} \quad \mathbb{G}_{n,kc}f(x_{it}) := \frac{\sqrt{N}}{N} \sum_{(m,t):(g,c,t) \in I_k^c} [f(x_{it}) - \mathbb{E}f(x_{it})]
\]

The summation in each \( a_{kc}, b_{kc} \) is by i.i.d groups \( g \in [G] \) and time \( t \in [T] \).
\[ e = \mathbb{E}_N(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))U_{it} = \frac{1}{K} \sum_{k=1}^{K} \mathbb{E}_{n,ke}(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))U_{it} \]

\[ f = \mathbb{E}_N(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))R_{it} = \frac{1}{K} \sum_{k=1}^{K} \mathbb{E}_{n,ke}(d_{i,0}(Z_{it}) - \hat{d}_i(Z_{it}))R_{it} \]

\[ g = \mathbb{E}_N \tilde{D}_{it}R_{it} = \frac{1}{K} \sum_{k=1}^{K} \mathbb{E}_{n,ke} \tilde{D}_{it}R_{it} \]

**Step 2.** Conditionally on \( I_k^c \),

\[ \mathbb{E}[e_{kc}|I_k^c] = 0, \quad \mathbb{E}[g_{kc}|I_k^c] = 0 \]

**Step 3.**

\[ n\mathbb{E}[e_{kc}^2|(W_{it})_{i \in I_k^c}] = \mathbb{E}_{Z_{it}}[\mathbb{E}[(\hat{D}_{it})^2|Z_{it}, (W_{it})_{i \in I_k^c}]|((\hat{d}_k(Z_{it}) - d_k(Z_{it}))^2|(W_{it})_{i \in I_k^c}] \leq \sigma^2 d \mathbf{m}_N^2 \]

\[ n\mathbb{E}[g_{kc}^2|(W_{it})_{i \in I_k^c}] = \mathbb{E}_{Z_{it}}[\mathbb{E}[\tilde{D}_{it}^2|Z_{it}, (W_{it})_{i \in I_k^c}]|(R_{it})^2|(W_{it})_{i \in I_k^c}] \leq \mathbf{d}_N^2 + d^2 \mathbf{m}_N^2 \beta_0 \]

**Step 4.** Conditionally on \( I_k^c \),

\[ \mathbb{E}[|f_{kc}||I_k^c] \leq d \mathbf{m}_N^2 \beta_0 + \sqrt{d} \mathbf{m}_N \mathbf{I}_N \]

\[ \sqrt{n}(f_{kc} - \mathbb{E}[f_{kc}|((W_{it})_{i \in I_k^c})|(W_{it})_{i \in I_k^c}] \leq \sqrt{n} \lambda_N \sqrt{d} \]

Markov inequality implies:

\[ \sqrt{n}e_{kc} = o_P(\sigma \sqrt{d} \mathbf{m}_N), \]

\[ \sqrt{n}f_{kc} = o_P(\sqrt{N} \sqrt{d} \mathbf{m}_N \mathbf{I}_N + \sqrt{N} d \mathbf{m}_N^2 \beta_0 + \sqrt{d} \lambda_N), \]

\[ \sqrt{n}g_{kc} = o_P(\sqrt{d} \mathbf{I}_N + d \mathbf{m}_N \beta_0) \]

By Markov inequality,

\[ \mathbb{E}_N[\tilde{D}_{it}[R_{it} + U_{it}] - \hat{D}_{it}U_{it}]^2 \leq \mathbb{E}_N[(\hat{D}_{it} - \hat{D}_{it})R_{it}]^2 + \mathbb{E}_N[(\hat{D}_{it} - \hat{D}_{it})U_{it}]^2 \]

\[ + \mathbb{E}_N[\tilde{D}_{it}^2 R_{it}]^2 \leq [d \mathbf{m}_N^2 \beta_0 \leq + \mathbf{I}_N] dD^2 + d \mathbf{m}_N^2 \sigma^2 \]

**Proof of Lemma** Let \( (a_{kc})_{k=1}^K, (b_{kc})_{k=1}^K \) be as defined in (Proof E). The errors are computed on \( k \in [K] \) partition for the cluster \( c \in [C] \)

51
Step 1

\[ \hat{Q} - \tilde{Q} = \frac{1}{KC} \sum_{k=1}^{K} \sum_{c=1}^{C} \left[ \mathbb{E}_{n,kc}(\tilde{D}_{it})(d_{i,0}(Z_{it}) - \hat{d}_{i}(Z_{it}))' + a'_{kc} \right] \]

\[ + \mathbb{E}_{n,kc}(d_{i,0}(Z_{it}) - \hat{d}_{i}(Z_{it}))(d_{i,0}(Z_{it}) - \hat{d}_{i}(Z_{it}))' \]

(E.3)

Step 2

\[ \mathbb{E}[a_{kc}|\{Z_{it}, (W_{it})_{i\in I^e_k}\}] = 0 \]

Step 3 By definition of \( m_N \),

\[
\max_{1 \leq m, j \leq d} \mathbb{E}[b_{kc}|(W_{it})_{i\in I^e_k}]_{m,j} = \max_{1 \leq m, j \leq d} \left| \mathbb{E}[(d_{i,0}(Z_{it}) - \hat{d}_{i}(Z_{it}))(d_{i,0}(Z_{it}) - \hat{d}_{i}(Z_{it}))'(W_{it})_{i\in I^e_k}] \right|_{m,j} \\
\leq m^2_N
\]

Step 4 Fix the hold-out sample \( I^e_k \). Conditionally on \( I^e_k \), \( a_{kc} \) is mean zero \( d \times d \) matrix with bounded entries. Azouma-Hoeffding inequality for martingale difference sequence implies:

\[
\mathbb{E}\left[ \max_{1 \leq m, j \leq d^2} |E_{n}a_{kc}|_{m,j}|(W_{it})_{i\in I^e_k}\right] \leq D^2 \sqrt{\frac{\log(2d^2)}{N}}
\]

Assumption 3.2 implies

\[
\mathbb{E}\left[ \max_{1 \leq m, j \leq d^2} |E_{n}b_{kc} - E[b_{kc}|(W_{it})_{i\in I^e_k}]|_{m,j}|(W_{it})_{i\in I^e_k}\right] \leq \lambda_N
\]

\[
\max_{1 \leq m, j \leq d^2} |E_{n}a_{kc}|_{m,j} = O_P(D^2 \sqrt{\frac{\log(2d^2)}{N}})
\]

\[
\max_{1 \leq m, j \leq d^2} |E_{n}b_{kc} - E[b_{kc}|(W_{it})_{i\in I^e_k}]|_{m,j} = \lambda_N
\]

\[
\max_{1 \leq m, j \leq d} |a + a' + b|_{m,j} \leq \sum_{k=1}^{K} \max_{1 \leq m, j \leq d} |a_{kc} + a'_{kc} + b_{kc}|_{m,j} \\
\leq \rho \, K \left[ m_N^2 + D^2 \sqrt{\frac{\log(2d^2)}{N}} + \lambda_N \right]
\]

52
Proof of Lemma D.3. For every $\delta = \hat{\beta} - \beta_0, \delta \in \mathbb{R}^d$ we use the notation:

$$\|\delta\|_{2,N} = (E_N(\hat{\mathbb{D}}_i^t\mathbb{D})^2)^{1/2}$$

and the in-sample prediction error with respect to estimated residuals by

$$\|\delta\|_{\hat{\mathbb{d}},2,N} = (E_N(\hat{\mathbb{D}}_i^t\mathbb{D})^2)^{1/2}$$

The bound on the difference between $\|\delta\|_{\hat{\mathbb{d}},2,N}$ and $\|\delta\|_{2,N}$ is as follows:

$$\|\delta\|_{\hat{\mathbb{d}},2,N}^2 - \|\delta\|_{2,N}^2 = \delta' E_N \hat{\mathbb{D}}_i^t \hat{\mathbb{D}}_i^t - E_N \hat{\mathbb{D}}_i^t \hat{\mathbb{D}}_i^t \delta \\
\geq -q_N \|\delta\|_1^2$$

By definition of $RE(\bar{c})$, for all $\delta \in RE(\bar{c})$ the following holds:

$$\|\delta\|_{\hat{\mathbb{d}},2,N}^2 - \|\delta\|_{2,N}^2 \geq -q_N \|\delta\|_1^2$$

$$\geq -q_N((1 + \bar{c})|\delta_T|_1)^2$$

$$\geq -q_N \frac{(1 + \bar{c})^2 s}{\kappa(Q, T, \bar{c})^2} \|\delta\|_{2,N}^2$$

Therefore,

$$\sqrt{1 - q_N \frac{(1 + \bar{c})^2 s}{\kappa(Q, T, \bar{c})^2}} \leq \frac{\|\delta\|_{\hat{\mathbb{d}},2,N}}{\|\delta\|_{2,N}} \leq \sqrt{1 + q_N \frac{(1 + \bar{c})^2 s}{\kappa(Q, T, \bar{c})^2}}$$

This implies a bound on $\kappa(\hat{Q}, T, \bar{c})$:

$$\kappa(\hat{Q}, T, \bar{c}) : = \min_{\delta \in RE(\bar{c})} \frac{\sqrt{3} \|\delta\|_{\hat{\mathbb{d}},2,N}}{\|\delta_T\|_1}$$

$$\leq \min_{\delta \in RE(\bar{c})} \frac{\sqrt{3} \|\delta\|_{2,N}}{\|\delta_T\|_1} \sqrt{1 + q_N \frac{(1 + \bar{c})^2 s}{\kappa(Q, T, \bar{c})^2}}$$

$$\sqrt{\kappa(Q, T, \bar{c})^2 - (1 + \bar{c})^2 s} \leq \kappa(\hat{Q}, T, \bar{c}) \leq \sqrt{\kappa(Q, T, \bar{c})^2 + (1 + \bar{c})^2 s}$$

Proof of Lemma D.4. Let

$$\hat{Y}_{it} = \hat{D}_i^t \beta_0 + R_{it} + U_{it}$$
where
\[ R_{it} = (\hat{d}_i(Z_{it}) - d_{i,0}(Z_{it}))' \beta_0 + (l_0(Z_{it}) - \hat{l}_i(Z_{it})), i \in \{1, 2, ..., N\} \]
summarizes first stage approximation error.

**Step 1** Define the following quantities:
\[ e_{k,m} = \mathbb{E}_{n,kc}(\hat{a}_{m,0}(Z_{it}) - d_{m,0}(Z_{it}))U_{it} \]
\[ f_{k,m} = \mathbb{E}_{n,kc}(\hat{a}_{m,0}(Z_{it}) - d_{m,0}(Z_{it}))R_{it} \]
\[ g_{k,m} = \mathbb{E}_{n,kc} \hat{D}_{it}R_{it} \]

**Step 2** Conditionally on \( I^c_k \), \( \mathbb{E}[e_{k,m}|I^c_k] = 0 \) \( \forall k \in [K], m \in [d], \mathbb{E}[g_{k,m}|I^c_k] = 0 \).

**Step 3** Conditionally on \( I^c_k \),
\[ \mathbb{E}[f_{k,m}|I^c_k] \leq \sup_{(d,l) \in (D_N,L_N)} \max_{1 \leq m \leq d} (\mathbb{E}(d_{m}(Z_{it}) - d_{i,0}(Z_{it}))^2)^{1/2}(\mathbb{E}(R_{it})^2)^{1/2} \leq m_N[m_N \sqrt{s} \vee l_N] \]

**Step 4** Conditionally on \( I^c_k \), the terms \( e_{kc}, g_{kc} \) and demeaned term \( (f_{k,m})^0 = f_{k,m} - \mathbb{E}[f_{k,m}|I^c_k] \) are bounded by maximal inequality for conditional expectation. Since the bound in RHS does not depend on \( I^c_k \), the bound is also unconditional.

\[ \mathbb{E}[\max_{1 \leq m \leq d} \|e_{k,m}\||I^c_k] = O(\sigma D \sqrt{\frac{\log d}{N}}), \]
\[ \mathbb{E}[\max_{1 \leq m \leq d} \|(f_{k,m})^0\||I^c_k] = O(\lambda_N), \]
\[ \mathbb{E}[\max_{1 \leq m \leq d} \|g_{k,m}\||I^c_k] = O([D^2 s + DL] \sqrt{\frac{\log d}{N}}) \]

Therefore,
\[ \mathbb{E}[\max_{1 \leq m \leq d} \|e_m\|] = O(\sigma D \sqrt{\frac{\log d}{N}}), \]
\[ \mathbb{E}[\max_{1 \leq m \leq d} \|(f_m)^0\|] = O([D^2 s + DL] \sqrt{\frac{\log d}{N}}), \]
\[ \mathbb{E}[\max_{1 \leq m \leq d} \|g_m\|] = O(\lambda_N) \]
Definition E.1 (First Stage Lasso-Panel). Let $\eta^Y = [\eta^Y_1, ..., \eta^Y_N]'$ and $\eta^D = [\eta^D_1, ..., \eta^D_N]'$ be vector of individual heterogeneity parameters in outcome (Equation 2.1) and treatment (Equation 2.3), respectively. For every index $k$ in the set of partition indices $[K]$, let

$$\hat{Q}_k(\alpha^D, \gamma^D, \eta^D) = \sum_{(i,t) \in I^c_k} (D_{i,t} - Z'_{i,t} \gamma^D - \eta^D_{it})^2$$

(E.5)

$$\hat{Q}_k(\alpha^Y, \gamma^Y, \eta^Y) = \sum_{(i,t) \in I^c_k} (Y_{i,t} - Z'_{i,t} \gamma^Y - \eta^Y_{it})^2$$

(E.7)

Let $s_{\eta^Y}, s_{\eta^D}, s_{\gamma^Y}, s_{\gamma^D}$ denote the sparsity indices of $\eta^Y, \eta^D, \gamma^Y, \gamma^D$, respectively.

Theorem E.1 (Rate of First Stage Lasso-Panel). Let $\lambda^D = \lambda^Y = \left((4M^2N\log(p \vee N))^3) \right)^{1/2}$ for each partition $k \in [K]$. By Theorem 1 from [Kock and Tang, 2016] the following rates hold with high probability:

$$\|\hat{\eta}^D_k - \eta^D_0\|_1 \lesssim_p \frac{\lambda^D s_{\eta^D}}{\kappa_2^2 \sqrt{NT}}$$

$$\|\hat{\gamma}^Y_k - \gamma^Y_0\|_1 \lesssim_p \frac{\lambda^Y s_{\eta^D}}{\kappa_2^2 \sqrt{NT}}$$

$$\|\hat{\gamma}^Y_k - \gamma^Y_0\|_1 \lesssim_p \frac{\lambda^Y s_{\gamma^Y}}{\kappa_2^2 N}$$

$$\|\hat{\gamma}^D_k - \gamma^D_0\|_1 \lesssim_p \frac{\lambda^D s_{\gamma^D}}{\kappa_2^2 N}$$

Corollary E.1 (Convergence of approximation error). Suppose the components controls $Z_{i,t}$ are a.s. bounded:

$$\|Z_{i,t}\|_\infty \leq C_Z$$

Then, the following out-of-sample squared approximation error of treatment and outcome reduced form exhibits the following bound:

$$\mathbb{E}_N(\tilde{p}_k(Z_{i,t}) - p_0(Z_{i,t}))^2 \lesssim_p \frac{\max(s^2_{\eta^D}, s^2_{\gamma^D}) \log^3(p \vee N)}{N}$$
and

\[ E_N(\hat{l}_k(Z_{i,t}) - l_0(Z_{i,t}))^2 \lesssim_{P} \frac{\max(s_{\gamma Y}^2, s_{\eta Y}^2) \log^3(p \vee N)}{N} \]

Denote

\[ \sqrt{d} m_N = \frac{\max(s_{sD}, s_{sY}) \log^{3/2}(p \vee N)}{\sqrt{N}} \]

and

\[ l_N = \frac{\max(s_{sY}, s_{sY}) \log^{3/2}(p \vee N)}{\sqrt{N}} \]

**Proof of Corollary 4.7** Fix a partition \( k \in [K]. \) The choice of \( \lambda^D = \lambda^Y = \sqrt{N \log(p \vee N)} \) yields the following bound:

\[
a_{kc} = \frac{1}{N} \sum_{(i,t) \in I_k} (\hat{l}_k(Z_{i,t}) - d_0(Z_{i,t}))^2 = \frac{1}{N} \sum_{(i,t) \in I_k} (Z_{i,t}(\hat{\gamma}_D^D - \gamma_D^0) + \hat{\eta}_t - \eta_t)^2 \\
\leq \frac{2}{N} \sum_{(i,t) \in I_k} (Z_{i,t}(\hat{\gamma}_D^D - \gamma_D^0))^2 + \|\hat{\eta}^D - \eta_D^0\|_2^2 / N \\
\leq 2\|Z_{i,t}\|_\infty^2 \|\hat{\gamma}_D^D - \gamma_D^0\|_1^2 + \|\hat{\eta}^D - \eta_D^0\|_2^2 / N \\
\leq \|Z_{i,t}\|_\infty^2 \frac{2\lambda^D s_{sD}^2}{\kappa^2(\sqrt{N})^2} + \lambda^D s_{sD}^2 \lesssim_P d m_N^2
\]

\[
b_{kc} = \sum_{(i,t) \in I_k} (\hat{l}_k(Z_{i,t}) - l_0(Z_{i,t}))^2 = \frac{1}{N} \sum_{(i,t) \in I_k} (Z_{i,t}(\hat{\gamma}_Y^Y - \gamma_Y^0) + \hat{\eta}_t - \eta_t)^2 \\
\leq \frac{2}{N} \sum_{(i,t) \in I_k} (Z_{i,t}(\hat{\gamma}_Y^Y - \gamma_Y^0))^2 + \|\hat{\eta}^Y - \eta_Y^0\|_2^2 / N \\
\leq 2\|Z_{i,t}\|_\infty^2 \|\hat{\gamma}_Y^Y - \gamma_Y^0\|_1^2 + \|\hat{\eta}^Y - \eta_Y^0\|_2^2 / N \\
\leq \|Z_{i,t}\|_\infty^2 \frac{2\lambda^Y s_{sY}^2}{\kappa^2(\sqrt{N})^2} + \lambda^Y s_{sY}^2 \lesssim_P l_N^2
\]

Since \( K \) is a fixed finite number, \( \sum_{k=1}^K a_{kc} \lesssim_P d m_N^2 \) and \( \sum_{k=1}^K b_{kc} \lesssim_P l_N^2 \)
F Supplementary Statements without Proof

Example 6 (Smooth Function). Let $D$ be a scalar variable. Suppose the regression function $E[Y|Z, D]$ is additively separable in $D$ and controls $Z$:

$$Y = m_0(D) + g_0(Z) + U, \quad E[U|Z, D] = 0$$

where the target function $m_0 \in \Sigma(\mathcal{X}, s)$ belongs to Holder $s$-smoothness class. Let the series terms $\{p_m(\cdot)\}_{m=1}^{d}$ with the sup-norm $\xi_d \equiv \sup_{D \in D} \|p(D)\|_2$. Define $\beta_0$ as best linear preditor of $m_0$:

$$m_0(D) = \sum_{m=1}^{d} p_m(D) \beta_0 + V, \quad E[p(D_i,t)V_{i,t}] = 0$$

where $V$ is design approximation error with $L^2$ rate $r_d \to 0, d \to \infty$. Then, replacing Assumption 3.6 by a modified growth condition $\frac{\xi_d^2 \log N}{N} = o(1)$ yields the following $L^2$ rate on $\hat{m}(D) = \sum_{m=1}^{d} p_m(D) \hat{\beta}$:

$$\|\hat{\beta} - \beta\|_2 \lesssim_P \sqrt{\frac{d}{N}} + \frac{dm_N^2}{N} \|\beta_0\| + l_N \sqrt{d m_N} \sqrt{d m_N} \|\beta_0\| + r_d$$

$$\|\hat{m} - m\|_{F,2} \lesssim_P \sqrt{\frac{d}{N}} + \frac{dm_N^2}{N} \|\beta_0\| + l_N \sqrt{d m_N} \sqrt{d m_N} \|\beta_0\| + r_d$$

Remark F.1 (Double Robustness in DML framework). Orthogonal Least Squares is not doubly robust, since it places quality requirements on each of the treatment and outcome rates. In case one of the treatment or outcome reduced form is misspecified ($\sqrt{d m_N} \not\to 0$ or $l_N \not\to 0$), the estimator is inconsistent. A less stringent requirement is to ask for at least one regression to be correctly specified, namely:

$$l_N \sqrt{d m_N} = o(1)$$

This property is called double robustness. A doubly robust version of DML estimator can be obtained as follows:

Definition F.1 (Doubly Robust DML (DRDML)). Let $(W_{i,t})_{i=1}^{N} = (Y_{i,t}, D_{i,t}, Z_{i,t})_{i=1}^{N}$ be a random sample from law $P_N$. Let the estimated values $(\hat{d}(Z_{i,t}), \hat{l}(Z_{i,t}))_{i=1}^{N}$ satisfy 3.1. Define Doubly Robust DML estimator:

$$\hat{\beta}_{DR} = \hat{\beta}_{DR,(\hat{d}, \hat{l})} = (E_N[D_{i,t} - \hat{d}(Z_{i,t})][D_{i,t}])^{-1}E_N[D_{i,t} - \hat{d}(Z_{i,t})][Y_{i,t} - \hat{l}(Z_{i,t})]$$
**Theorem F.1** (Rate of DRDML). Let Assumptions 3.1, 3.2, 3.4, 3.3, 3.5 hold. Assume there is no approximation error $R = 0$. Then, w.p. $\rightarrow 1$,

$$\|\hat{\beta}_{DR} - \beta\|_2 \lesssim_{\mathcal{P}} t_N \sqrt{d_m N} + \sqrt{\frac{d}{N}}$$
