ABSTRACT

Large-scale star formation in disk galaxies is hypothesized to be driven by global gravitational instability. The observed gas surface density is commonly used to compute the strength of gravitational instability, but according to this criterion, star formation often appears to occur in gravitationally stable regions. One possible reason is that the stellar contribution to the instability has been neglected. We have examined the gravitational instability of the Large Magellanic Cloud considering the gas alone, and considering the combination of collisional gas and collisionless stars. We compare the gravitationally unstable regions with the ongoing star formation revealed by Spitzer observations of young stellar objects. Although only 62% of the massive young stellar object candidates are in regions where the gas alone is unstable, some 85% lie in regions unstable due to the combination of gas and stars. The combined stability analysis better describes where star formation occurs. In agreement with other observations and numerical models, a small fraction of the star formation occurs in regions with gravitational stability parameter $Q > 1$. We further measure the dependence of the star formation timescale on the strength of gravitational instability, and quantitatively compare it to the exponential dependence expected from numerical simulations.

1. INTRODUCTION

Observations of nearby galaxies suggest that there exists a gas surface density threshold for star formation in a galactic disk (Kennicutt 1989; Martin & Kennicutt 2001). This threshold is hypothesized to be formed by the threshold for gravitational stability of the disk, although alternative explanations have been offered (e.g., Schaye 2004). Gravitationally unstable regions are commonly identified by the Toomre criterion (Toomre 1964; Goldreich & Lynden-Bell 1965), which considers the stability of a single-component disk against axisymmetric perturbations. However, this criterion, when applied to observed gas surface densities, does not always correctly predict the locations of star formation (e.g., Martin & Kennicutt 2001; Wong & Blitz 2002). Stellar contribution to the gravitational instability could be important; for example, the giant molecular clouds in the Large Magellanic Cloud (LMC) have been shown to correlate with stellar surface density, indicating the increase of star formation toward regions of higher stellar gravity (Fukui 2007).

To crudely include the stellar contribution, Jog & Solomon (1984) derived the stability criterion for a two-fluid disk. This stability criterion differs from the Toomre criterion by only a linear correction factor, when the gas-to-stellar ratios of surface density and velocity dispersion are constant across a galaxy, or when the gas and stellar components are only weakly coupled (Wang & Silk 1994). To correctly include the stellar contribution, Gammie (1992) and Rafikov (2001) analyzed the stability of a composite disk consisting of a collisional gas component and a population of collisionless stellar components. The resulting instability criterion has been used to explain the dust morphology of edge-on disk galaxies (Dalcanton et al. 2004).

We study the relationship between gravitational stability and star formation in the LMC. The LMC is chosen because high linear resolution can be obtained (1" corresponds to 0.25 pc at 50 kpc; Feast 1999), its internal and foreground extinctions are small, and its moderate inclination allows spatial and kinematical mapping of the disk with minimum confusion along the line of sight. Both stars and the interstellar medium (ISM) of the LMC have been extensively surveyed. Recent Spitzer Space Telescope observations have been used to identify massive young stellar objects (YSOs), which mark the sites of current star formation (R. A. Gruendl et al., in preparation; B. A. Whitney et al., in preparation). Massive YSOs provide better probes than H ii regions to study the relationship between the ISM and star formation because their stellar energy feedback has not significantly altered the distributions and physical conditions of the ambient ISM.

In this paper we investigate the relationship between global star formation and gravitational instability in the LMC using two different stability analyses: assuming that the gaseous disk is decoupled from the stellar disk and considering only the gravity of the gas (§ 2.1), or assuming a collisionless stellar disk and a collisional gas disk and using the Rafikov (2001) stability criterion (§ 2.2). The results are discussed in § 3.
2. GRAVITATIONAL INSTABILITY

2.1. Gas Alone

A thin, differentially rotating gaseous disk is unstable against axisymmetric perturbations when

\[ Q_g \equiv \frac{\kappa c_g}{\pi G \Sigma_g} < 1, \]  

(1)

where \( Q_g \) is generally referred to as the Toomre \( Q \) parameter for a gaseous disk, \( \kappa \) is the epicyclic frequency, \( c_g \) is the isothermal sound speed of the gas, \( G \) is the gravitational constant, and \( \Sigma_g \) is the unperturbed surface density of the gas (Goldreich & Lynden-Bell 1965).

To apply this analysis to a disk galaxy, approximations need to be made. First, rather than consisting of a single isothermal component, the real ISM consists of gas with temperatures ranging from 10 to 10^7 K in multiple phases, including cold atomic and molecular, warm atomic and ionized, and hot ionized gas. However, the gas mass is dominated by cold atomic and molecular material in turbulent motion, except possibly in star-forming regions where much of the ISM is ionized. Therefore, we consider only the neutral atomic and molecular gas mass. The atomic medium of galaxies generally has nearly constant velocity dispersion (van der Kruit & Shostak 1982; Shostak & van der Kruit 1984; Dickey et al. 1990; Petric & Rupen 2007), and has a vertical thickness that is well modeled by assuming hydrostatic equilibrium with the gravitational potential at the velocity dispersion (e.g., Malhotra 1995). We assume the gas disk of the LMC has an effective sound speed representative of the velocity dispersion \( c_g = 5 \) km s\(^{-1}\) (Dib et al. 2006; Petric & Rupen 2007). Second, \( \Sigma_g \) in equation (1) is the unperturbed gas surface density, while the observed gas surface density is perturbed. The surface density of a gravitationally unstable region grows exponentially as it collapses; thus, using the observed surface density in equation (1) will correctly diagnose gravitationally unstable regions, but \( Q_g \) may be underestimated if collapse has set in. Therefore, we adopt the observed gas surface density for \( \Sigma_g \) in equation (1) to identify gravitationally unstable regions.

The neutral atomic and molecular components of the ISM in the LMC have been well surveyed. For the neutral atomic component, we use the \( \text{H} \text{i} \) column density map derived from the combined data set of the Australia Telescope Compact Array and the Parkes multi-beam receiver (Kim et al. 2003). This \( \text{H} \text{i} \) map has a resolution of \( \sim 1' \), or 15 pc. For the molecular component, we use the NANTEN CO survey of the LMC conducted by Fukui et al. (1999, 2001). These maps have a resolution of \( \sim 2'6 \), or 40 pc. We scale maps of integrated column density by the CO-to-H\(_2\) conversion factor, \( X = 5.4 \times 10^{20} \) H\(_2\) atoms cm\(^{-2}\) (K km s\(^{-1}\))\(^{-1}\) (Blitz et al. 2007) to obtain the H\(_2\) mass distribution. Both the \( \text{H} \text{i} \) and H\(_2\) maps are clipped at the 1 \( \sigma \) level to prevent negative densities and minimize the effects of noise. Furthermore, we account for He and heavier elements by assuming that the mass fraction of H is \( X \sim 0.7 \). From the \( \text{H} \text{i} \) map, we find a total mass for the neutral atomic component of \( 5.1 \times 10^8 \) \( M_\odot \), consistent with the value found by Kim et al. (1998).

For the molecular component, we find a total mass of \( 6.6 \times 10^7 \) \( M_\odot \), which is on the high side of the \((4-7) \times 10^7 \) \( M_\odot \) given by Mizuno et al. (1999, 2001) as we used a higher CO-to-H\(_2\) conversion factor and included He and heavy elements. We add these two maps to obtain a map of total gas surface density with a resolution of 40 pc pixel\(^{-1}\). The resulting map is shown in Figure 1a.

The remaining parameter needed in equation (1) is the epicyclic frequency \( \kappa \), defined by

\[ \kappa^2 = \frac{2V^2}{R^2} \left(1 + \frac{R}{V} \frac{dV}{dR}\right), \]

(2)

where \( R \) is the galactocentric distance and \( V = V(R) \) is the circular velocity as a function of \( R \). To calculate \( \kappa \) at a given \( R \) in the LMC, we use the rotation curve derived by Kim et al. (1998). The rotation curve is a best-fit to the \( \text{H} \text{i} \) and the carbon star (Kunkel et al. 1997) measurements inside and outside of about 3.2 kpc, respectively. We find the derivatives of the circular velocity and thus the epicyclic frequency by central finite differences with an increment of 250 pc, then we use a cubic spline to interpolate the discrete results to a continuous domain. Finally, the center and the orientation of the disk of the LMC need to be specified. To be consistent with the \( \text{H} \text{i} \) kinematics, we adopt the same center and orientation determined by Kim et al. (1998).

The kinematic center of the LMC disk is at \( \alpha = 05^h 17.6^m \) and \( \delta = -69^\circ 02' \) (J2000.0) with an inclination of \( i = 33^\circ \) and a line of nodes at a P.A. of \(-12^\circ\). Using this geometry, the total gas surface density map is deprojected to determine the galactocentric distance of each pixel, allowing us to construct a map of \( Q_g \) calculated from equation (1). This map is shown in Figure 1b.

The contours in Figure 1b delineate the critical boundary \( Q_g = 1 \) that surrounds regions gravitationally unstable due to gas alone. Also marked in the figure are candidate massive YSOs from R. A. Grundel et al. (in preparation), indicating regions of on-going star formation. In the top panel of Figure 2, we show the number distribution of YSO candidates and the corresponding cumulative fraction with respect to \( Q_g \). While \( <62\% \) (153 of 245) of the YSO candidates do lie in regions with \( Q_g < 1 \), the rest are distributed in regions with values as high as \( Q_g \sim 3 \).

Some of the candidates with \( Q_g < 1 \) might be argued not to result from large-scale gravitational instabilities because the unstable regions in which they reside are too small. If we exclude regions \( \leq 100 \) pc in diameter, only \( 47\% \) (116) of the YSO candidates would be associated with gravitationally unstable regions by this criterion. A frequently used empirical correction for the contributions from the stellar component (Jog & Solomon 1984; Wang & Silk 1994) and the effect of the disk scale height (Jog & Solomon 1984) is to raise the critical value to \( Q_g \sim 1.4 \) (Kennicutt 1989; Martin & Kennicutt 2001). Even if we apply this linear correction factor to the Toomre criterion, \( <25\% \) of the YSO candidates still appear to reside in stable regions. Considering the stability of only the gas disk or applying a simple linear correction to the Toomre criterion may not be sufficient to account for star formation activity.

2.2. Gas and Stars Together

We now also consider the contribution of stars to gravitational instability. To include them, we follow Rafikov’s (2001) treatment of a disk galaxy consisting of a collisional gas disk and a collisionless stellar disk. The instability condition becomes

\[ \frac{1}{Q_{gs}} = \frac{2}{Q_{gs}} \left[1 - e^{-x^2 I_0(a^2)}\right] + \frac{2}{Q_{gs}} \frac{R}{1 + q^2 R^2} > 1. \]

(3)

In equation (3), \( Q_{gs} \) is the stability parameter for the gas derived by Goldreich & Lynden-Bell (1965) as defined in equation (1), while

\[ Q_{gs} = \frac{\kappa \Sigma_s}{\pi G \Sigma_s} \]

(4)
is the stability parameter for the stars derived by Toomre (1964), where $\sigma_s$ is the stellar radial velocity dispersion, $\Sigma_s$ is the stellar surface density; $R \equiv c_s/\sigma_s$, and $q \equiv k\sigma_s/\kappa$ are two dimensionless parameters, with $k$ being the wavenumber of the axisymmetric perturbations; and $I_0$ is the Bessel function of order zero.

Similarly to our procedure in § 2.1, we use local observed values to evaluate $Q_{\text{st}}$. To estimate the stellar surface density $\Sigma_s$, we use the number density of red giant branch (RGB) and asymptotic giant branch (AGB) stars, as they are part of the old stellar population and therefore trace the overall mass distribution of the stellar disk. RGB and AGB stars are luminous and distinctive in the $[J - K_s]$ versus $K_s$ color-magnitude diagram and much less confused by faint background galaxies or Galactic stars. To select these stars, we follow a procedure similar to that outlined by van der Marel (2001) but use only the Two Micron All Sky Survey Point Source Catalog (Skrutskie et al. 2006) and the criteria $[J - K_s] < (22 - [K_s])/10.5$ and $[K_s] < 14.5$. The source counts are then binned with a resolution of 40 pc pixel$^{-1}$ and Gaussian smoothed with a dispersion of 100 pc. The smoothing scale is chosen to minimize pixel-to-pixel variations due to the small number density of the tracer RGB and AGB stars, while retaining good spatial resolution for the analysis; this scale is also small compared

---

**Fig. 1.**—(a) Total gas surface density distribution in the Large Magellanic Cloud. Only neutral species are included in this map. The gray-scale runs linearly from 0 to $100 \, M_\odot \, \text{pc}^{-2}$. The contour lines show a surface density of $4 \, M_\odot \, \text{pc}^{-2}$. (b) Comparison between massive star-forming sites traced by young stellar object candidates (red dots) and regions where the gas alone is gravitationally unstable. The Toomre parameter for the gas $Q_g$ is shown in gray-scale, running logarithmically from 5.0 to 0.2. The solid lines delineate the critical value of $Q_g \equiv 1$ inside which the regions are gravitationally unstable. (c) Total stellar surface density distribution. The gray-scale runs linearly from 0 to $200 \, M_\odot \, \text{pc}^{-2}$. (d) Same as in (b), but for regions where the gas and stars together are gravitationally unstable, rather than just the gas alone.
to the large-scale gravitational instability in the analysis. In the resulting map, a faint Galactic background with a gradient is present. Therefore, we fit and subtract this background with exponential and linear dependencies on the Galactic latitude and longitude, respectively. Finally, by adopting the total stellar mass of $2 \times 10^9 M_\odot$, estimated by Kim et al. (1998) we normalize this map to obtain the absolute stellar surface density map shown in Figure 1c (see Fig. 2 of van der Marel 2001). We adopt a constant stellar radial velocity dispersion of 15 km s$^{-1}$, after considering the velocity dispersions of carbon stars (Kunkel et al. 1997; Alves & Nelson 2000; Graff et al. 2000; van der Marel et al. 2002), red supergiants (Prevot et al. 1989; Olsen & Massey 2007), and young globular clusters (Freeman et al. 1983).

With these values assessed, the parameter $Q_{\text{st}}$ defined in equation (3) now depends only on the perturbation wavenumber $k$, or equivalently, the perturbation wavelength $\lambda = 2\pi/k$ at each pixel (see Fig. 3). Since $Q_{\text{st}}$ decreases with the degree of gravitational instability and our objective is to locate gravitationally unstable regions, we define its value at each pixel as its global minimum with respect to $\lambda$. The derived $Q_{\text{st}}$ map of the LMC is shown in Figure 1d, with the identified YSOs overlaid.

Each point is unstable to perturbations over a finite range of wavelengths, as shown by Figure 3. If the size of a gravitationally unstable region is smaller than the minimum unstable wavelength $\lambda_{\text{min}}$, no perturbation inside the region can have long enough wavelength to drive an instability. Therefore, we also find $\lambda_{\text{min}}$ in each pixel, and compare this value with the size of each region containing YSO candidates by visual inspection. The contours of $Q_{\text{st}} = 1$ are plotted over gray-scale presentations of $\lambda_{\text{min}}$ in Figure 4 so that the sizes of the $Q_{\text{st}} < 1$ regions can be compared with the minimum unstable wavelengths directly.

Figure 1d shows that, because of the stellar contribution, a much larger fraction of the galaxy is unstable than would have been deduced just from the gas contribution shown in Figure 1b. The vast majority of the massive YSO candidates are in fact located within gravitationally unstable regions, in sharp contrast to the results in $\S$ 2.1, where only the gas is considered. Particularly noticeable is the vicinity of the LMC bar region, where on-going star formation is observed. This bar region, having low gas surface densities and high epicyclic frequencies, is stable when only the gas disk is considered, but becomes unstable when the stellar component is added. The bottom panel of Figure 2 shows the number distribution of YSO candidates and the corresponding cumulative fraction with respect to $Q_{\text{st}}$. About 86% (212 of 245) of the YSO candidates are located in regions where $Q_{\text{st}} < 1$. Figure 4 shows 12 of the 212 YSOs in probably stable regions having $Q_{\text{st}} < 1$ but region size $< \lambda_{\text{min}}$. Removing these 12 still leaves 82% of the YSOs whose formation is attributed to gravitational instability of the disk of stars and gas. One caution is that finite thickness of the disk may lower the critical $Q_{\text{st}}$ value slightly, depending on the scale height of the disk relative to the unstable wavelengths (Jog & Solomon 1984). Given an estimated scale height of $\sim 180$ pc (Kim et al. 1999) and kiloparsec-scale unstable wavelengths in the LMC, this effect may be small. The results

![Figure 2](image1.png)  
![Figure 3](image2.png)  
![Figure 4](image3.png)
demonstrate that the stellar contribution to gravitational instability can be significant. Gravitational instability of the full disk appears responsible for most large-scale star formation activity.

3. DISCUSSION AND CONCLUSIONS

Schaye (2004) has argued that a constant gas surface density threshold is a good indicator in predicting the edge of the star-forming disk. He suggested that, for the LMC disk, this threshold is \( \sim 4 M_\odot \text{ pc}^{-2} \). Figure 1a shows the contours of \( 4 M_\odot \text{ pc}^{-2} \) in total neutral gas surface density. The contours encompass the majority of the LMC disk except the central cavities of the supergiant shells LMC-4 and LMC-8 (Meaburn 1980). Clearly, all the massive YSO candidates are located where the gas surface density is greater than \( 4 M_\odot \text{ pc}^{-2} \), but this constant surface density threshold does not account for the distribution of the star-forming sites, especially in the inner parts of the LMC disk. Therefore, Schaye’s (2004) constant surface density threshold is a necessary but not sufficient condition for star formation. Detailed analysis of the large-scale gravitational instability, as shown in § 2, is still needed.

Another measure of the response of star formation to disk instability is the relation between \( Q_{sg} \) and the effective timescale for star formation \( \tau_{sf} \). This can be approximated if we assume the average lifetime of massive YSOs is constant. We normalize the number of YSOs, \( N_s \), within a region having a given range of \( Q_{sg} \) by the area, as represented by the total number of pixels \( N_{pix} \) within that region. Figure 5 presents \( N_s/N_{pix} \), which is \( \propto \tau_{sf}^{-1} \), for a number of \( Q_{sg} \) bins. The errors in the ratio are estimated assuming Poisson statistics on the number of YSOs and number of pixels, while the horizontal error bars show the size of the bins. A clear log-linear relationship is found, implying that the response of star formation depends exponentially on the value of \( Q_{sg} \). Li et al. (2005) also found an exponential dependence \( \tau_{sf} \propto \exp(aQ_{sg}) \), with \( a = 4.2 \pm 0.3 \) from global numerical simulations of galactic disks. A linear fit to the data in Figure 5 gives a slope that can be interpreted as a local value of \( a = 2.7 \pm 0.2 \). This behavior appears to be a general property of nonlinear gravitational instability.

We have made the simple assumption that the structure of the LMC is a thin, flat disk with negligible stellar halo. In reality, tidal features due to galaxy-galaxy interactions do exist in the outer parts of the disk (e.g., van der Marel 2001). Furthermore, at some locations, there exist multiple \( H_i \) velocity components, which we have simply summed to obtain total gas surface density. Other uncertainties stem from our assumed constant gas effective sound speed (or velocity dispersion) and stellar radial velocity dispersion. These affect the relative contribution of each component to the gravitational instability: the higher the local velocity dispersion, the less contribution a component has. The sound speed of the gas we adopt, 5 km s\(^{-1}\), is a typical average for the neutral gas. The radial velocity dispersion of stars is also uncertain. As gravitational instability is much more sensitive to the gas component due to its low sound speed, it is less affected by the uncertainty in the stellar velocity dispersion. Yet another effect to consider is the scale height of the disk, which tends to stabilize the disk (Toomre 1964; Jog & Solomon 1984). Given all these uncertainties, nevertheless, the exponential dependence of star formation rate on \( Q_{sg} \) that we find appears to be robust.

From our analysis of the gravitational instability of the LMC, we conclude that the contribution of the stellar disk to gravitational instability cannot be ignored (Jog & Solomon 1984; Gammie 1992; Rafikov 2001). Taking it into account in the case of the LMC, we find that \( \sim 85\% \) of the massive YSO candidates lie in gravitationally unstable regions, implying that star formation occurs predominantly in these regions. It appears that gravitational instability of the disk drives most large-scale star formation, as proposed by Elmegreen (2002), Kravtsov (2003), and Li et al. (2005).

This research was supported by NASA grants JPL1264494 and JPL1290956, and NSF grant AST03-07854. We would like to thank Charles Gammie for his feedback and discussions in this work. We also thank the anonymous referee for the prompt review and useful suggestions.
