Abstract

The ability to continuously learn and adapt itself to new tasks, without losing grasp of already acquired knowledge is a hallmark of biological learning systems, which current deep learning systems fall short of. In this work, we present a novel methodology for continual learning called MERLIN: Meta-Consolidation for Continual Learning. We assume that weights of a neural network ψ, for solving task t, come from a meta-distribution ρ(ψ|t). This meta-distribution is learned and consolidated incrementally. We operate in the challenging online continual learning setting, where a data point is seen by the model only once. Our experiments with continual learning benchmarks of MNIST, CIFAR-10, CIFAR-100 and Mini-ImageNet datasets show consistent improvement over five baselines, including a recent state-of-the-art, corroborating the promise of MERLIN.

1 Introduction

The human brain is able to constantly, and incrementally, consolidate new information with existing information, allowing for quick recall when needed [5, 77]. In this natural setting, it is not common to see the same data sample multiple times, or even twice at times. Human memory capacity is also limited which forbids memorizing all examples that are seen during its lifetime [39]. Hence, the brain operates in an online manner, where it is able to adapt itself to continuously changing data distributions without losing grasp of its previously acquired knowledge [33]. Unfortunately, deep neural networks have been known to suffer from catastrophic forgetting [52, 25], where they fail to retain performance on older tasks, while learning new tasks.

Continual learning is a machine learning setting characterized by its requirement to have a learning model incrementally adapt to new tasks, while not losing its performance on previously learned tasks. Note that ‘task’ here can refer to a set of new classes, new domains (e.g. thermal, RGB) or even new tasks in general (e.g. colorization, segmentation) [62, 67, 83]. The last few years have seen many efforts to develop methods to address this setting from various perspectives. One line of work constrains the parameters of the deep network trained on Task A to not change much while learning a new Task B, while another - replay-based methods - store or generate examples of previous tasks to finetune the final model at evaluation time. Another kind of methods attempt to expand the network to increase the capacity of the model, while learning new tasks. Broadly speaking, all these methods manipulate the data space or the weight space in different ways to achieve their objectives.

In this work, we propose a different perspective to addressing continual learning, based on the latent space of a weight-generating process, rather than the weights themselves. Studies of the human brain suggest that knowledge and skills to solve tasks are represented in a meta-space of concepts with a high-level semantic basis [28, 10, 50]. The codification from tasks to concepts, and the periodic consolidation of memory, are considered essential for a transferable and compact representation of knowledge that helps humans continually learn [11, 84, 5]. Current continual learning methods consolidate (assimilate knowledge on past tasks) either in the weight space [13]
We consider weights of a neural network $\psi$, which can solve a specific task, to come from a meta-distribution $p(\psi|t)$, where $t$ is a representation for the task. We propose a methodology to learn this distribution, as well as continually adapt it to be competent on new tasks by consolidating this meta-space of model parameters whenever a new task arrives. We refer to this process as “Meta-Consolidation”. We find that continually learning in the parameter meta-space with consolidation is an effective approach to continual learning. Learning such a meta-distribution $p(\psi|t)$ provides additional benefits: (i) at inference time, any number of models can be sampled from the distribution $\psi_t \sim p(\psi|t)$, which can then be ensembled for prediction in each task (Sec 4.1.3); (ii) it is easily adapted to work in multiple settings such as class-incremental and domain-incremental continual learning (Sec 4), and (iii) it can work in both a task-aware setting (where the task is known at test time) and task-agnostic setting where the task is not known at test time (achieved by marginalizing over $t$, Sec 5.2). Being able to take multiple passes through an entire dataset is an assumption that most existing continual learning methods make [2, 38, 47, 57, 62, 12]. Following [4, 3, 14, 48], we instead consider the more challenging (and more natural) online continual learning setting where ‘only a single pass through the data’ is allowed. We compare MERLIN against a recent state-of-the-art GSS [4], as well as well-known methods including GEM [48], iCaRL [62] and EWC [38] on Split MNIST [13], Permuted MNIST [87], Split CIFAR-10 [87], Split CIFAR-100 [62] and Split Mini-Imagenet [15] datasets. We observe consistent improvement across the datasets over baseline methods in Sec 4.

The key contributions of this work can be summarized as: (i) We introduce a new perspective to continual learning based on the meta-distribution of model parameters, and their consolidation over tasks arriving in time; (ii) We propose a methodology to learn this distribution using a Variational Auto-encoder (VAE) [37] with learned task-specific priors, which also allows us to ensemble models for each task at inference; (iii) We show that the proposed method outperforms well-known benchmark methods [48][62][38], as well as a recent state-of-the-art method [4], on five continual learning datasets; (iv) We perform comprehensive ablation studies to provide a deeper understanding of the proposed methodology and showcase its usefulness. To the best of our knowledge, MERLIN is the first effort to incrementally learn in the meta-space of model parameters.

2 Related Work

In this section, we review existing literature that relate to our proposed methodology from two perspectives: continual learning and meta-learning. We also discuss connections to neuroscience literature in the Appendix.

Continual learning methods: In continual learning, when a new task $t_k$ comes by, the weights of the associated deep neural network, $\psi_{t_k}$, get adapted for the new task causing the network to perform badly on previously learned tasks. To overcome this issue (called catastrophic forgetting [52][23]), one family of existing efforts [2, 38, 47, 87] force the newly learned weight configuration $\psi_{t_k}$, to be close to the previous weight configuration $\psi_{t_{k-1}}$, so that the performance on both tasks are acceptable. This approach, by design, can restrict the freedom of the model to learn new tasks. Another set of methods [14, 62, 48, 12] store a few samples (called exemplars) in a fixed-size, task-specific episodic memory, and use strategies like distillation [31] and finetuning to ensure that $\psi_{t_k}$ performs well on all tasks seen so far. These methods work at the risk of memorization. Shin et al. [73] instead used a generative model to synthesize examples for all the previous tasks, which allows generating infinite data for the seen tasks. However, as more tasks are added, the capacity of the model reduces, and the generative model does not work well in practice. A recent group of methods [51, 71, 68] attempt to expand the network dynamically to accommodate learning new tasks. While this is an interesting approach, the model size in such methods can increase significantly, hampering scalability.

The aforementioned methods operate in an offline fashion, wherein once data for a specific task is available, it can be iterated over multiple times to learn the task. In contrast, online continual learning methods [4, 3, 14, 38] tackle a more challenging setting, closer to how humans operate, where all datapoints are seen only once during the lifetime of the model. [4, 3] proposes methods to choose

38, 47, 16, 87, 55, 2, 70] or in the data space [14, 62, 73, 48, 5, 45, 65]. Even meta-learning based continual learning methods that have been proposed in the recent past [54, 24, 6, 63], meta-learn an initialization amenable for quick adaptation across tasks, similar to MAML [23], and hence operate in the weight space. We propose MERLIN: Meta-Consolidation for Continual Learning, a new method for continual learning that is based on consolidation in a meta-space, viz. the latent space which generates model weights for solving downstream tasks.
optimal training datapoints for learning continually, which they found is critical in an online continual learning setting, while [14, 48] constrains the learning of the new task, such that the loss on the previously learned class should not increase. We refer the interested reader to [17, 58] for a detailed survey of current continual learning methods and practices. Contrary to these methods, we propose a new perspective to continual learning based on meta-consolidation in the parameter space which has its own benefits as mentioned earlier.

**Meta-learning methods:** Meta-learning encapsulates a wide variety of methods that can adapt to new tasks with very few training examples. Meta-learning algorithms - which mostly have focused on the standard learning setting (not continual learning) - can be broadly classified into black-box adaptation based methods [69, 54], optimization based [23, 56, 89] and non-parametric methods [82, 74, 76]. Hypernetworks [27] is one black-box adaptation method where a meta-neural network is used to predict the weights of another neural network. This opened up an interesting research direction, in exploiting the meta-manifold of model parameters for multi-task learning [66], neural architecture search [8], zero-shot learning [57, 81] and style transfer [72] in recent years. One can view our approach as having a similar view to online continual learning (which has not been done before), although our methodology of learning the distribution of weights of the network is different from [27] and allows more flexibility in sampling and generating multiple models at inference. The work closest to ours is by Johannes et al. [83], which recently tried using HyperNetworks in the context of continual learning. We differ from [83] in the following ways: (i) we operate in the more natural and challenging online continual learning setting, while they use multiple passes over the data (ii) they learn a deterministic function which when conditioned on a task embedding, generates target weights, while we model the weight distribution itself, which allows us to sample as many model parameters at inference time and ensemble them, (iii) we can perform inference in a task-agnostic or task-aware manner, while they operate only in a task-aware setting.

### 3 MERLIN: Methodology

We begin by summarizing the overall methodology of MERLIN, as in Algorithm 1 and Figure 1. We consider a sequence of tasks $\tau_1$, $\tau_2$, $\cdots$, $\tau_{k-1}$ that have been seen by the learner, until now. A new task $\tau_k$ is introduced at time instance $k$. (Note that task can refer to a new class or a domain, both of which are studied in Sec 4.) Each task $\tau_j$, $j \in \{1, \cdots, k\}$ consists of $\tau_j^{train}$, $\tau_j^{valid}$ and $\tau_j^{test}$ corresponding to training, validation and test samples for that task. Each task $\tau_j$ is also represented by a corresponding vector $t_j$, as described in Sec 5.1. As the first step, we train a set of $B$ base models on random subsets of $\tau_k^{train}$ (sampled without replacement, note that this does not violate the online setting as this is done by choosing each streaming point with a certain probability in each base model) to obtain a collection of models $\Psi_k = \{\psi^1_k, \cdots, \psi^B_k\}$ (as in first section of Fig 1, line 2 in Algorithm 1). $\Psi_k$ is then used to learn a task-specific parameter distribution $p_{\phi}(\psi_k | t_k)$ using a VAE-like strategy further described in Sec 3.1. This is followed by a meta-consolidation phase, where we sample model parameters for all tasks seen so far, from the decoder of the VAE, each conditioned on a task-specific prior, and use them to refine the overall VAE, as described in Sec 3.2. At inference, we sample models from the parameter distributions for each task, and use them to evaluate on the test data following the methodology described in Sec 3.3. A set of $\psi$s are sampled from $p_{\phi}(\psi_k | t_k)$ for task $t_k$ and ensembled to obtain the final result. We now describe each of the components below.

#### 3.1 Modeling Task-specific Parameter Distributions:
Each task $\tau_j$ is represented by a corresponding vector representation $t_j$. Our framework allows any fixed-length vector representation for this task descriptor, including semantic embeddings such as GloVe [60] or Word2Vec [53], or

| Step | Description |
|------|-------------|
| 1. | Sample $(x, y)$ from $\tau$ |
| 2. | Train base network |
| 3. | Learn the parameter distribution |
| 4. | Consolidate using Algorithm 2 |
| 5. | Sample model parameters and ensemble |

Figure 1: Overview of MERLIN. While learning a new task $\tau_k$ at time $k$, $B$ models are trained and saved to $\Psi_k$. These weights are used to learn a task-specific parameter distribution with task-specific priors in Step 3. In Step 4, the model is consolidated by replaying parameters generated using earlier task-specific priors as in Algorithm 3. At test time, model parameters are sampled from $p_{\phi}(\phi | z, t)$ and ensembled.
simply a one-hot encoding of the task. A richer embedding such as Task2Vec [11], which takes into
account task correlations, may also be used. Details of our implementation are deferred to Sec 4. We
consider $\psi_j$, the weights of a neural network which can solve a task $t_j$, as generated by a random
process given by a continuous latent variable $z$, i.e. $\psi_j$ is generated from $p_\theta(\cdot | z, t)$, where $z$
is sampled from a conditional prior distribution $p_\theta(\cdot | z)$ (We denote the $j^{th}$ task, $t_j$ as $t$ for simplicity
of explaining the model in this subsection). $\theta^*$ refers to the unknown optimal parameters of the
weight-generating distribution, which we seek to find. We achieve this objective using a VAE-like for-
mulation [37], adapted for this problem. Computing the marginal likelihood of the weight distribution
$p_\theta(\psi | t) = \int p_\theta(\psi | z, t) p_\theta(z | t) dz$ is intractable as its true posterior $p_\theta(z | \psi, t) = p_{\phi_\theta}(z | \psi, t) p_\theta(z | t)$ is
intractable to compute. We introduce the approximate posterior $q_\phi(\cdot | z, t)$, parametrized by $\phi$, as
a variational distribution for the intractable true posterior $p_\theta(z | \psi, t)$. The marginal likelihood
of the parameter distribution, $\log p_\theta(\psi | t)$, can then be written as (please refer the Appendix
for the complete derivation):

$$ \log p_\theta(\psi | t) = D_{KL}(q_\phi(z | \psi, t) \| p_\theta(z | \psi, t)) + \int q_\phi(z | \psi, t) \log \frac{p_\theta(z | \psi, t)}{q_\phi(z | \psi, t)} $$(1)

where the second term is the expected negative reconstruction error. The KL divergence term on the
RHS forces the approximate posterior of weights to be close to a task-specific prior $p_\theta(z | t)$. Note
that this differentiates this formulation from a conditional VAE [36], where the latents are directly
conditioned. In our model, the latents are conditioned indirectly through priors that are conditioned
on task vectors. Assuming $q_\phi(.)$ and $p_\theta(.)$ to be Gaussian distributions, the KL divergence
term can be computed in closed form. The second term requires sampling, and the model parameters,
$\phi$ and $\theta$, are trained using the reparameterization trick [37], backpropagation and Stochastic Gradient Descent.

Instead of choosing the prior to be an isotropic multivariate Gaussian $p_\theta(z) = N(z | 0, I)$ as in a
vanilla VAE, we use a learned task-specific prior, $p_\theta(z | t)$, given by:

$$ p_\theta(z | t) = N(z | \mu_t, \Sigma_t) \text{ where } \mu_t = W^T_{\mu} t \text{ and } \Sigma_t = W_{\Sigma}^T t $$ (3)

Here, $W_{\mu}$ and $W_{\Sigma}$ are parameters which are learned alongside $\phi$ and $\theta$, when maximizing the
lower bound (Eqn 2) using backpropagation. We find that a simple linear model is able to learn $W_{\mu}$
and $W_{\Sigma}$, effectively, as revealed in our experiments.

As already stated, the probabilistic encoder $q_\phi(z | \psi, t)$ and decoder $p_\theta(\psi | z, t)$ are materialized
using two neural networks parametrized by $\phi$ and $\theta$ respectively. To train these, we consider
$\Psi_j = \{ \psi_j^b \}_{b=1}^B$, a set of $B$ model parameters that are obtained by training on the $j^{th}$ task by sampling
the corresponding training data without replacement. These models are now used to learn the
“meta-parameters” $\phi$ and $\theta$, as well as $\mu_t$ and $\Sigma_t$ of the Gaussian prior, specific to the task. At
inference, one can sample as many $\psi$’s (task-specific models) as needed from the decoder using
different samples from the task-specific prior. Obtaining a model $\psi$ for each task $t$ from the parameter
distribution $p_\theta(\psi | z, t)$, is a two-step process: (i) Sample $z$ from task-specific prior distribution
i.e. $z \sim N(z | \mu_t, \Sigma_t)$; (ii) Sample $\psi$ from the probabilistic decoder, using $z$ i.e. $\psi \sim p_\theta(\psi | z, t)$.
Note that we have only a single VAE model, which can generate network parameters for each task
individually by conditioning the VAE on the corresponding task-specific prior.

3.2 Meta-consolidation: When the continual learner encounters the $k^{th}$ task and receives the set
of optimal model parameters for this task $\Psi_k = \{ \psi_k^b \}_{b=1}^B$, directly updating the VAE on $\Psi_k$ alone

---

**Algorithm 1** MERLIN: Overall Methodology

**Input:** Tasks: $\mathcal{T} \equiv \{ \tau_1 \cdots \tau_k \}$; Task training data: $\tau_j^T = \{(x_i, y_i)\}_{i=1}^{N_j^T}$; # of base models: $B$

1: for $j = 1$ to $|\mathcal{T}|$ do
2: $\Psi_j \leftarrow$ Train $B$ models by randomly sub-sampling training data from $\tau_j^T$
3: Learn task parameter distribution and task specific prior using methodology in Sec 3.1 and $\Psi_j$
4: Consolidate using methodology in Sec 3.2, Algorithm 2
5: Perform inference on $\mathcal{T}$, using methodology in Sec 3.3, Algorithm 3
Algorithm 2 Meta-consolidation in MERLIN

Input: Encoder: \( q_\phi (z|\psi, t) \); Decoder: \( p_\theta (\psi|z, t) \); Last seen task: \( \tau_k \); Task priors: \( \{ P_i \}_{i=1}^k = (\mu_i, \Sigma_i) \); # of pseudo-models: \( P \)

Output: Consolidated encoder-decoder parameters: \( \phi \) and \( \theta \)

1: for \( j = 1 \) to \( k \) do
2: \( \mu_j, \Sigma_j \leftarrow P_j \) \hspace{1cm} \triangleright Task specific \( z_j \)
3: \( z_j \sim \mathcal{N}(z|\mu_j, \Sigma_j) \)
4: \( \text{Loss} \leftarrow \sum_{i=1}^k \mathcal{L}(\theta, \phi|\psi_j, t) \) where \( \psi_j \sim p_\theta (\psi|z_j, t) \) \hspace{1cm} \triangleright \mathcal{L}(.) \) is defined in Equation 2
5: \( g \leftarrow \nabla_{\theta, \phi} \text{Loss} \)
6: \( \phi, \theta \leftarrow \text{Update parameters } \phi, \theta \text{, using gradient } g. \)
7: return \( \phi, \theta \)

3.3 Inference: Having learned the distribution to generate model parameters for each task seen until now, the learned task-specific priors give us the flexibility to sample any number of models from this distribution at inference/test time. This allows for ensembling multiple models at test time (none of which need to be stored a priori), which is a unique characteristic of the proposed method.

Ideally, a continual learning algorithm should be able to solve all tasks encountered so far, without access to any task-specific information at inference time. While a handful of existing methods [29][62] take this into consideration, many others [48][38][87] assume availability of task-identifying information during inference. This is also referred as single-head or multi-head evaluation in literature [13][76][24]. Our methodology works with both evaluation settings, which we refer to as task-agnostic and task-aware inference, as described below. Algorithm 3 outlines the inference steps. We use the consolidated decoder \( p_\theta (\psi|z, t) \), and task-specific priors \( P \) at test time. In a task-agnostic setting, a single overall prior distribution is aggregated from all task-specific priors. We find that a simple averaging of parameters of the prior distributions works well in practice. The latent variable \( z \) is sampled from this aggregated prior. The model parameters sampled from the decoder using \( z \) has the capability to solve all tasks seen till then. The generated \( \psi \) is amenable for quick adaptation to each task similar to MAML [23] to obtain task-dependent model parameters. To leverage this, we store a
We note a distinction between tasks in “Split” versions of the datasets and Permuted MNIST. In “Split” settings, while the latter as 4.1.2 Base Classifier Architecture: For CIFAR and Mini-ImageNet datasets, a modified ResNet [30] architecture is used, which is 10 layers deep and has fewer number of feature maps in each of the four residual blocks (5, 10, 20, 40). This reduces the number of parameters from 0.27M to 34997. In spite of using a weaker base network (owing to computing constraints), our method outperforms baselines, as shown in our results. For the MNIST dataset, we use a two-layer fully connected neural network with 100 neurons each, with ReLU activation, following the experimental setting in GEM [48]. To train these base models (which are then used to train the VAE), an initial learning rate of 0.001 and weight decay of 0.001. To ensure the online setting, the model is trained only for a single epoch, similar to baseline methods [48, 4] used in the weight space; GEM [48], GSS [4], and iCaRL [62] use exemplar memory and consolidate in the data space; while MERLIN consolidates in the meta-space of parameters. We used the official implementations of each of these baseline methods for fair comparison. Five standard continual learning benchmarks, viz. Split MNIST [13], Permuted MNIST [87], Split CIFAR-10 [87], Split CIFAR-100 [62] and Split Mini-Imagenet [15], are used in the experiments, following recent continual learning literature [12, 4, 62, 51, 13].

4 Experiments and Results
We evaluate MERLIN against prominent methods for continual learning: GEM [48], iCaRL [62], EWC [38], a recent state-of-the-art GSS [4], and a crude baseline where a single model is trained across tasks (referred to as ‘Single’ in our results). GSS and EWC are inherently designed for online continual learning, while iCaRL and EWC are easily adapted to this setting following [48, 14]. These baselines consolidate in different spaces: EWC [38], a regularization-based method, consolidates in the weight space; GEM [48], GSS [4], and iCaRL [62] use exemplar memory and consolidate in the data space; while MERLIN consolidates in the meta-space of parameters. We used the official implementations of each of these baseline methods for fair comparison. Five standard continual learning benchmarks, viz. Split MNIST [13], Permuted MNIST [87], Split CIFAR-10 [87], Split CIFAR-100 [62] and Split Mini-Imagenet [15], are used in the experiments, following recent continual learning literature [12, 4, 62, 51, 13].

4.1 Experimental Setup: We describe the datasets, evaluation metrics and other implementation details below, before presenting our results. Our code is implemented in PyTorch [59] and runs on a single NVIDIA V-100 GPU.

4.1.1 Datasets: We describe the datasets considered briefly below (a detailed description is presented in the Appendix):

Split MNIST and Permuted MNIST: Subsequent classes in the MNIST [43] dataset are paired together and presented as a task in Split MNIST, a well-known benchmark for continual learning. This results in 5 incremental tasks. In Permuted MNIST, each task is a unique spatial permutation of 28 × 28 images of MNIST. 10 such permutations are generated to create 10 tasks. We use 1000 images per task for training and the model is evaluated on the all test examples, following the protocol in [48].

Split CIFAR-10 and Split CIFAR-100: 5 and 10 tasks are created by grouping together 2 and 10 classes from CIFAR-10 [41] and CIFAR-100 [41] datasets respectively. Following [48], 2500 examples are used per task for training. Trained models are evaluated on the whole test set.

Split Mini-Imagenet: Mini-Imagenet [82] is a subset of ImageNet [18] with a total of 100 classes and 600 images per class. Each task consists of 10 disjoint subset of classes from these 100 classes. Similar to CIFAR variants, 2500 examples per task is used for training, as in [15].

We note a distinction between tasks in “Split” versions of the datasets and Permuted MNIST. In “Split” datasets, the label space expands with tasks, while for Permuted MNIST, the data space changes with tasks without changing the label space. The former is referred to as the Class-Incremental setting, while the latter as Domain-Incremental setting in literature [32, 79]. MERLIN works on both settings.

4.1.2 Base Classifier Architecture: For CIFAR and Mini-ImageNet datasets, a modified ResNet [30] architecture is used, which is 10 layers deep and has fewer number of feature maps in each of the four residual blocks (5, 10, 20, 40). This reduces the number of parameters from 0.27M to 34997. In spite of using a weaker base network (owing to computing constraints), our method outperforms baselines, as shown in our results. For the MNIST dataset, we use a two-layer fully connected neural network with 100 neurons each, with ReLU activation, following the experimental setting in GEM [48]. To train these base models (which are then used to train the VAE in MERLIN), batch size is set to 10 and Adam [35] is used as the optimizer, with an initial learning rate of 0.001 and weight decay of 0.001. To ensure the online setting, the model is trained only for a single epoch, similar to baseline methods [48, 4] used in the weight space; GEM [48], GSS [4], and iCaRL [62] use exemplar memory and consolidate in the data space; while MERLIN consolidates in the meta-space of parameters. We used the official implementations of each of these baseline methods for fair comparison. Five standard continual learning benchmarks, viz. Split MNIST [13], Permuted MNIST [87], Split CIFAR-10 [87], Split CIFAR-100 [62] and Split Mini-Imagenet [15], are used in the experiments, following recent continual learning literature [12, 4, 62, 51, 13].
4.1.3 Task Descriptors: The inputs to train models for each task are training data points \( \tau_k \in \mathbb{R}^D \) corresponding to task \( \tau_k \). As in Sec 3.1, in order to condition the prior distribution \( p_{\theta}(z|t) \) on a task, each task, \( \tau_k \), is represented by a corresponding fixed-length task descriptor \( t_k \in \mathbb{R}^k \). We use the simplest approach in our experiments: one-hot encoding of the task sequence number. Using semantic task descriptors such as GloVe or Word2Vec can allow our framework to be extended to few-shot/zero-shot continual learning. The label embedding of a zero/few-shot task can be used to condition the prior, which can subsequently generate helper decoder models for the zero/few-shot task. We leave this as a direction of future work at this time.

4.1.4 Training the VAE: The first step of MERLIN is to train task-specific classification models from training data \( \tau_k \) using the abovementioned architectures. The weights of these models are used to train the VAE. 10 models are learned for each task by random sampling of subsets (with replacement) from \( \tau_k \). Considering that base classification models can be large, in order to not make the VAE too large, we use a chunking trick proposed by Johannes et al. in [83]. The weights of the base classification models are flattened into a single vector and split into equal sized chunks (last chunk zero-padded appropriately). We use a chunk size of 300 for all experiments, and show a sensitivity analysis on the chunk size in Sec 5.5. The VAE is trained on the chunks (instead of the full models) for scalability, conditioned additionally on the chunk index. At inference, the classifier weights are assembled back by concatenating the chunks generated by the decoder, conditioned on the chunk index. We observed that this strategy worked rather seamlessly, as shown in our results. The approximate posterior \( q_{\phi}(z|\psi, t) \), is assumed to be a 2-D isotropic Gaussian, whose parameters are predicted using a encoder network with 1 fully connected layer of 50 neurons, followed by two layers each predicting the mean and the covariance vectors. The decoder \( p_{\theta}(\psi|z, t) \) mirrors the encoder’s architecture. The network that generates the mean and diagonal covariance vectors of the learned prior, as in Eqn 3, is modeled as a linear network. AdaGrad [20] is used as the optimizer with an initial learning rate of 0.001. Batch size is set to 1 and the VAE network is trained for 25 epochs.

4.1.5 Inference: At test time, we sample 30 models from the trained decoder \( p_{\theta}(\psi|z, t) \) to solve each task. Algorithm 3 shows how these are obtained for task-aware and task-agnostic settings. These models are ensembled using majority voting. An ablation study varying the number of sampled models at inference is presented in Sec 5.5. We ensure that this adds minimal inference overhead by loading sampled weights into the model sequentially and saving only the final logits for ensembling. Hence, only one model is stored at a given time in memory, allowing our framework to scale up effectively. Any additional steps in our methodology is offset by the choice of very small models to train, and our chunking strategy, leading to minimal overhead in training time over the baseline methods. At test time, our method is real-time, and has no difference from baseline methods.

4.1.6 Evaluation Metrics: For all experiments, we consider the average accuracy across tasks and average forgetting measure as the evaluation criteria, following previous works [13, 48]. Average accuracy (A \( \in [0, 100]\)) after learning the \( k^{th} \) task (\( \tau_k \)), is defined as \( A_k = \frac{1}{k} \sum_{j=1}^{k} a_{k,j} \), where \( a_{k,j} \) is the performance of the model on the test set of task \( j \), after the model is trained on task \( k \). Forgetting is defined as the difference in performance from the peak accuracy of a model learned exclusively for a task and the accuracy of the continual learner on the same task. Average forgetting measure \( F \in [-100, 100] \) after learning the \( k^{th} \) task can be defined as \( F_k = \frac{1}{k-1} \sum_{j=1}^{k-1} \max_{l \in \{1, ..., k-1\}} (a_{l,j} - a_{k,j}) \). We ran each experiment with five different seed values and report the mean and standard deviation.

4.2 Results: Table 1 shows how MERLIN compares against baseline methods on all the considered datasets. iCaRL [62] results are not reported for Permuted MNIST as it is not a Domain-Incremental methodology. We see that the average accuracy (higher is better) obtained by MERLIN shows significant improvement over baseline methods across datasets and settings. The difference is larger.
with increasing complexity of the dataset. MERLIN also shows strong improvement in the forgetting metric on most datasets, including a negative value (showing improved performance on earlier tasks, known as positive backward transfer [14]) on Split CIFAR10. While learning a new task, iCaRL uses distillation loss [31] to ensure that logits of exemplars from the previous tasks, do not alter much with the current task learning. This, we believe, helps iCaRL achieve lower forgetting, when compared to other methods. MERLIN is able to outperform iCaRL too, in two out of four datasets, with reduced forgetting. GSS [4] failed on CIFAR-100 and Mini-ImageNet, even after we tried different hyperparameters. The original paper does not report results on these datasets. We did not include comparison with A-GEM [14] as it reports only marginal improvement over GEM [48]. The evolution of test accuracy with addition of tasks, which showed improvement in accuracy over the baselines from the very first task, is presented in the Appendix due to space constraints.

5 Discussions and Analysis
We analyze the effectiveness of MERLIN using more studies, as described below.

5.1 Is the Probabilistic Decoder Learning the Parameter Distribution? The key component of MERLIN is the decoder that models the parameter distribution $p_θ(ψ|z_t, t)$. Should the decoder fail to learn, then each model $ψ_t ∼ p_θ(ψ|z_t, t)$ would be an ineffective sample from an untrained decoder. In such a scenario, the only reason why inference (Alg 3) would work would be due to finetuning of these sampled models on the exemplars (L4, L10; Alg 4). In order to study this, we run an experiment where we intentionally skip training the VAE and the consolidation step that follows. With all other components the same, this corresponds to only finetuning with exemplars. The ‘w/o training VAE’ row in Tab 2 shows the results. Consistently, on all datasets, the performance drops significantly while removing this key component. This suggests that the proposed meta-consolidation through the VAE is actually responsible for the performance in Tab 1.

5.2 Task Agnostic vs Task Aware Inference: All results of MERLIN in Tab 1 do not assume task information during evaluation, and hence operate in the task-agnostic setting. MERLIN can work in both task-agnostic and task-aware settings, as shown in the last two rows of Tab 2. Expectedly, access to task information during inference boosts performance for simple datasets like Split MNIST. For other datasets, average accuracy and forgetting measure is almost similar for both. This supports our choice of aggregation strategy of priors across tasks, which captures the task-agnostic setting quite well.

| Datasets        | Split MNIST | Permuted MNIST | Split CIFAR-10 | Split CIFAR-100 | Split Mini-ImageNet |
|-----------------|-------------|----------------|---------------|-----------------|-------------------|
| Methods         | A (↑)       | F (↓)          | A (↑)         | F (↓)           | A (↑)            |
| w/o training VAE| 14.8 ± 5.7  | 19.9 ± 2.3     | 39 ± 4.7      | 5.8 ± 0.2       | 35.5 ± 6.6       |
| Task Agnostic   | 90.7 ± 0.8  | 64 ± 1.2       | 85.5 ± 0.5    | 0.4 ± 0.4       | 43.5 ± 0.6       |
| Task Aware      | 97.4 ± 0.3  | 0.1 ± 0.3      | 85 ± 1.4      | 1.1 ± 0.8       | 44.4 ± 2.8       |

Table 2: MERLIN variants: (i) without training VAE and subsequent consolidation (ii) Task-agnostic (iii) Task-aware MERLIN. Task-agnostic MERLIN performs almost as well as Task-aware MERLIN on several datasets.

5.3 Varying Number of Models for Ensembling: In Sec 4, we sampled 30 models for each task from the decoder used in MERLIN. We now vary the number of models in Tab 3. We observe a 3.98%, 6.34% and 8.99% improvement on Split-MNIST, Permuted-MNIST and Split Mini-ImageNet, when using 30 models for ensembling, over using only 1. The performance improvement however is not very significant on further increase beyond 30 models. This suggests that while ensembling is required, the number of models need not be very large. Improving our ensembling strategy (beyond majority voting) is a direction of our future work.

| # of models → | 1 | 30 | 50 | 100 |
|---------------|---|----|----|-----|
| Permed MNIST  | 86.6 ± 1.4 | 90.6 ± 0.8 | 91.4 ± 0.3 | 91.6 ± 0.3 |
| Permuted MNIST| 79.7 ± 3.9  | 85.4 ± 0.4  | 85.6 ± 0.3  | 85.7 ± 0.2  |
| Split Mini-ImageNet| 30.1 ± 1.8 | 39.1 ± 2.1  | 40.5 ± 2.9  | 40.9 ± 1.3  |

Table 3: Test accuracy with varying number of models in our inference ensemble.

5.4 Storage Requirements: MERLIN requires only parameters of task-specific prior $p_θ(z|t)$ and decoder of the VAE, at inference time. The encoder is required only if we need to continually learn further tasks. None of the components in the architecture grows with number of tasks, making MERLIN scalable. Quantitative analysis on the size of classifier and VAE (meta-model) is presented in Tab 4. We note that meta-model size is always smaller than classifier, and is $8 \times$ smaller than the storage size is always smaller than classifier, and is $8 \times$ smaller than the storage

| # of params in → | Clf | VAE |
|------------------|-----|-----|
| Split MNIST      | 89610 | 31426 |
| Permuted MNIST   | 89610 | 31446 |
| Split CIFAR-10   | 31307 | 17910 |
| Split CIFAR-100  | 34997 | 33810 |
| Split Mini-ImageNet | 34997 | 33810 |

Table 4: Num of params in classifier and VAE.
requirement of GSS, GEM, EWC and iCaRL which use ResNet-18 with 272,260 parameters. Similar to GEM, we maintain an exemplar buffer of 200 and 400 for MNIST and other datasets respectively.

5.5 Varying Chunk Size: As in Sec 4.1.4 we split the weight vector into equal-sized chunks before encoding it using VAE. We vary chunk size and report the average accuracy in Tab 5. As chunk size increases, the accuracy drops - we hypothesize this is to do with the capacity of VAE. We use simple architectures in our encoder-decoder, and modeling larger weight chunks (or whole models) may require more complex VAE.

Table 5: Avg test accuracy when varying chunk size.

| Chunk Size → | 100 | 300 | 1000 | 2000 |
|--------------|-----|-----|------|------|
| Split MNIST  | 90.8 ± 0.4 | 90.6 ± 0.8 | 87.5 ± 3.7 | 87.4 ± 2.2 |
| Permuted MNIST | 85.6 ± 0.4 | 85.5 ± 0.5 | 83.7 ± 2.8 | 82.5 ± 3.6 |
| Split Mini-ImageNet | 40.9 ± 1.2 | 40.5 ± 2.9 | 38.8 ± 2.8 | 37.8 ± 2.1 |

5.6 Varying Exemplar Memory Size We vary the memory size of the exemplar buffer for MERLIN, and compare the performance against our best competitors in Table 1 of the main paper: GEM [48] and iCaRL [62] in CIFAR-10 experiments. The results in Table 6 show that the increase in performance for MERLIN is significantly better when compared to GEM and iCaRL. We hypothesize this is because the weights sampled from our parameter distribution use these exemplars better, similar to how other meta-learning approaches like MAML [23] finetune on just a few samples. Using better exemplar selection methods other than random sampling (used in this work) can further enhance MERLIN, and is a direction of our future work.

Table 6: Results of varying memory size of exemplar buffer for MERLIN, GEM [48] and iCaRL [62].

| Memory Size → | 100 | 500 | 1000 | 2000 |
|---------------|-----|-----|------|------|
| GEM           | 77.4 ± 2.6 | 79.9 ± 1.9 | 80.9 ± 1.9 | 80.5 ± 1.5 |
| iCaRL         | 72.5 ± 2.6 | 73.6 ± 1.3 | 73.7 ± 2.6 | 74.8 ± 1.3 |
| MERLIN        | 77.9 ± 1.3 | 81.9 ± 0.3 | 86.9 ± 0.6 | 88.4 ± 0.8 |

6 Conclusion

We introduce MERLIN, a novel approach for online continual learning, based on consolidation in a meta-space of model parameters. Our method is modeled based on a VAE, however adapted to this problem through components such as task-specific learned priors. Our experimental evaluation on five standard continual learning benchmark datasets against five baseline methods brings out the efficacy of our approach. MERLIN can handle both class-incremental and domain-incremental settings, and can work with or without task information at test time. Understanding the dynamics of the latent space of the parameter distribution to further enhance memory retention and extending the methodology to a few-shot setting can be immediate follow-up efforts to MERLIN.

Acknowledgements

We thank TCS for funding Joseph through its PhD fellowship, and DST, Govt of India, for partly supporting this work through the IMPRINT program (IMP/2019/000250). We also thank the members of Lab1055, IIT Hyderabad and the ContinualAI community for the engaging and fruitful discussions, which helped to shape MERLIN.

Broader Impact

Continual learning is a key desiderata for Artificial General Intelligence (AGI). Hence, this line of research has the benefits as well as the pitfalls of any other research effort geared in this direction. In particular, our work can help deliver impact on making smarter AI products and services, which can learn and update themselves on-the-fly when newer tasks and domains are encountered, without forgetting previously acquired knowledge. This is a necessity in any large-scale deployments of machine learning and computer vision, including in social media, e-commerce, surveillance, e-governance, etc - each of which have newer settings, tasks or domains added continually over time. Any negative effect of our work, such as legal and ethical concerns, are not unique to this work - to the best of our knowledge, but are shared with any other new development in machine learning, in general.

Appendix: Meta-Consolidation for Continual Learning

In this appendix, we discuss the following details, which could not be included in the main paper owing to space constraints:

- Derivations of Equation 1 and Equation 2 in the main paper.
- Effect of adding an auxiliary classification loss while training the meta-model.
- A plot on the behavior of VAE training loss.
- A visualization of the latent space of the learned priors and the generated models.
- Further details of datasets used.
- Task-wise accuracies of the main results presented in Table I.
- Connections of MERLIN to neuroscience literature.
- Comparison with Bayesian continual learning methods.
- Efficacy of task-specific learned priors.
- Results while using smaller backbones for the baselines.
- 5 class-per-task experiments.
- Our code implementation of our methodology in Section 3.

A Estimating Marginal Likelihood

Let $q_\phi(z|\psi,t)$ be the approximation for the intractable true posterior distribution $p_\theta(z|\psi,t)$ as defined in Section 3.1. The KL Divergence between these two distributions, $D_{KL}(q_\phi(z|\psi,t) \parallel p_\theta(z|\psi,t))$ - written below as $D_{KL}(q \parallel p)$ for convenience - can be expressed as follows:

$$D_{KL}(q \parallel p) = - \int z q_\phi(z|\psi,t) \log \frac{p_\theta(z|\psi,t)}{q_\phi(z|\psi,t)}$$

$$= - \int z q_\phi(z|\psi,t) \log \frac{p_\theta(z|\psi,t)p_\theta(\psi|t)}{q_\phi(z|\psi,t)p_\theta(\psi|t)}$$

$$= - \int z q_\phi(z|\psi,t) \log \frac{p_\theta(z,\psi|t)}{q_\phi(z|\psi,t)} + \log p_\theta(\psi|t)$$

Rearranging, we get the marginal likelihood (Equation 1):

$$\log p_\theta(\psi|t) = D_{KL}(q_\phi(z|\psi,t) \parallel p_\theta(z|\psi,t)) + \int z q_\phi(z|\psi,t) \log \frac{p_\theta(z,\psi|t)}{q_\phi(z|\psi,t)}$$

B Alternate form of ELBO

The evidence lower bound (ELBO), $\mathcal{L}(\theta, \phi|\psi,t)$ - written below as $\mathcal{L}$ for convenience - derived in the above section, can be rewritten as follows:

$$\mathcal{L} = \int z q_\phi(z|\psi,t) \log \frac{p_\theta(z,\psi|t)}{q_\phi(z|\psi,t)}$$

$$= E_{q_\phi(z|\psi,t)} [-\log q_\phi(z|\psi,t) + \log p_\theta(z,\psi|t)]$$

$$= E_{q_\phi(z|\psi,t)} [-\log q_\phi(z|\psi,t) + \log p_\theta(\psi|z,t) + \log p_\theta(z|t)]$$

$$= E_{q_\phi(z|\psi,t)} [-\log q_\phi(z|\psi,t) + \log p_\theta(z|t)] + E_{q_\phi(z|\psi,t)} [\log p_\theta(\psi|z,t)]$$

$$= E_{q_\phi(z|\psi,t)} [\log p_\theta(z|t)] + E_{q_\phi(z|\psi,t)} [\log p_\theta(\psi|z,t)]$$

$$= - D_{KL}(q_\phi(z|\psi,t) \parallel p_\theta(z|t)) + E_{q_\phi(z|\psi,t)} [\log p_\theta(\psi|z,t)]$$

This is the expression of ELBO used in Equation 2.
C Minimizing ELBO and Classification Loss while Training VAE

The Evidence Lower-Bound (ELBO), defined in Equation 2, is maximized while training the VAE to learn the parameter distribution \( p(\psi|t) \) for all the experiments reported so far. We now introduce one more loss term to guide the training of VAE and study its usefulness. The weights that are generated from the decoder \( \psi \sim p_\theta(\psi|z_t, t) \), are used to initialize a classifier network. The loss for this network (computed on a training set of the classification dataset) is computed and also used to update the VAE.

Datasets → | Split MNIST | Permuted MNIST | Split CIFAR-10 | Split CIFAR-100 | Split Mini-ImageNet
--- | --- | --- | --- | --- | ---
Methods ↓ | A (↑) | F (↓) | A (↑) | F (↓) | A (↑) | F (↓) | A (↑) | F (↓) | A (↑) | F (↓)
ELBO | 90.7 ± 0.8 | 6.4 ± 1.2 | 85.5 ± 0.5 | 0.4 ± 0.4 | 82.9 ± 1.2 | 0.9 ± 1.9 | 43.5 ± 0.6 | 2.9 ± 3.7 | 40.1 ± 0.9 | 2.8 ± 3.2
ELBO + Clf Loss | 91.4 ± 0.2 | 6.1 ± 0.6 | 85.7 ± 0.3 | 0.8 ± 0.1 | 82.8 ± 1.1 | 0.2 ± 1.3 | 42.5 ± 1.2 | -1.1 ± 1.7 | 40.8 ± 2.6 | 0.9 ± 0.7

Table 7: Average accuracy (A) and average forgetting measure (F) while training MERLIN with and without an auxiliary classification loss. All results in the main paper were obtained by optimizing only the Evidence Lower-Bound (ELBO) as defined in Equation 2 to which this classification loss is now added.

We run MERLIN on all datasets after training with this additional loss term, and the results are reported in Table 7. We see that this adds some improvement on certain datasets, but is in general marginal (except forgetting measure on CIFAR-100 and Mini-ImageNet, which shows good improvement). This generally implies that the VAE is able to capture the task solving information implicitly, without explicit global loss to enforce this. However, in more complex datasets such as ImageNet, adding a classification loss can further improve performance.

D Loss Plots While Training VAE

We plot the loss curve while training the VAE in Figure 2. We observe that the VAE stabilizes fairly quickly, viz, within the first 10 epochs - further corroborating the usefulness of the proposed method. We plot the classification loss for completeness. The curve was plotted while training our method on the Permuted MNIST dataset.

![Figure 2](image-url)

Figure 2: Figure plots the ELBO, classification loss and the total loss against epochs. We see fair stability in the VAE training from the plot.

E Visualization of Task-specific Priors and Sampled Models:

![Figure 3](image-url)

Figure 3: (Left) Plot of 20 samples drawn from each task-specific prior \( z_t \sim p_\theta(z|t) \). (Right) t-SNE plot of weights obtained from decoder using corresponding \( z_t; \psi_t \sim p_\theta(\psi|z_t, t) \). Each color corresponds to 10 different tasks from split CIFAR100.
In Fig 5, we visualize the latent variables sampled from the learned prior distribution $z_t \sim p_\theta(z_t)$ (left) - which are two-dimensional themselves, and the 2D t-SNE embeddings \cite{49} of their corresponding model parameters generated using $z_t; \psi_t \sim p_\psi(z_t, t)$ (right). The model is trained on a 10 task split CIFAR-100 dataset. The separation of the latent samples and the task parameters of different models in the learned meta-space supports the usefulness of our method in overcoming catastrophic forgetting in continual learning.

### F Dataset Description

As shown in Section 4 of the main paper, we evaluate MERLIN against multiple baselines on Split MNIST \cite{13}, Permuted MNIST \cite{87}, Split CIFAR-10 \cite{87}, Split CIFAR-100 \cite{62} and Split Mini-ImageNet \cite{15} datasets. Table 8 provides a summary of these benchmark datasets and the corresponding tasks involved, as used commonly in continual learning literature \cite{15, 87, 62, 13} and in our work. The table enumerates different classes that form each task for class-incremental datasets.

| Dataset            | # of images per task | Tasks                                                                 |
|--------------------|----------------------|----------------------------------------------------------------------|
| Split MNIST \cite{15} | 1000                | $t_1 = \{1, 2\}$, $t_2 = \{3, 4\}$, $t_3 = \{5, 6\}$, $t_4 = \{7, 8\}$, $t_5 = \{9, 10\}$ |
| Permuted MNIST \cite{15} | 1000              | 10 different spatial permutations, each corresponding to a task. |
| Split CIFAR-10 \cite{87} | 2500              | $t_1 = \{airplane, automobile\}$, $t_2 = \{bird, cat\}$, $t_3 = \{deer, dog\}$, $t_4 = \{frog, horse\}$, $t_5 = \{ship, truck\}$ |
| Split CIFAR-100 \cite{87} | 2500              | $t_1 = \{beaver, dolphin, otter, seal, whale, aquarium fish, flatfish, ray, shark, trout\}$, $t_2 = \{orchard, poppy, roses, sunflowers, tulip, buttercup, daffodil, dandelion\}$, $t_3 = \{apple, mushrooms, oranges, pears, sweet peppers, clock, computer keyboard, lamp, telephone, television\}$, $t_4 = \{bed, chair, couch, table, wardrobe, bus, bed, butterfly, caterpillar, cactus\}$, $t_5 = \{bear, leopard, lion, tiger, wolf, bridge, castle, house, road, skyscraper\}$, $t_6 = \{cloud, forest, mountain, plain, sea, camel, cattle, chimpanzee, elephant, kangaroo\}$, $t_7 = \{fox, porcupine, pronghorn, raccoon, skunk, crab, lobster, small, spider, worm\}$, $t_8 = \{baby, boy, girl, man, woman, crocodile, dinosaur, lizard, snake, turtle\}$, $t_9 = \{hamster, mouse, rabbit, squirrel, spruce, maple, oak, palm, pine, willow\}$, $t_{10} = \{bicycle, bus, motorcycle, pickup truck, train, lane-marking, rocket, satellite, tank, tractor\}$ |
| Split Mini-ImageNet \cite{15} | 2500            | $t_1 = \{aardvark, camel, chimpanzee, elephant, giraffe, gorilla, horse, hyena, kangaroo\}$, $t_2 = \{high-bar, pole, miniskirt, muscle, poncho, coral reef, house finch, american robin, triceratops\}$, $t_3 = \{beaver, dolphin, otter, seal, whale, aquarium fish, flatfish, ray, shark, trout\}$, $t_4 = \{orchard, poppy, roses, sunflowers, tulip, buttercup, daffodil, dandelion\}$, $t_5 = \{apple, mushrooms, oranges, pears, sweet peppers, clock, computer keyboard, lamp, telephone, television\}$, $t_6 = \{bed, chair, couch, table, wardrobe, bus, bed, butterfly, caterpillar, cactus\}$, $t_7 = \{bear, leopard, lion, tiger, wolf, bridge, castle, house, road, skyscraper\}$, $t_8 = \{cloud, forest, mountain, plain, sea, camel, cattle, chimpanzee, elephant, kangaroo\}$, $t_9 = \{fox, porcupine, pronghorn, raccoon, skunk, crab, lobster, small, spider, worm\}$, $t_{10} = \{baby, boy, girl, man, woman, crocodile, dinosaur, lizard, snake, turtle\}$, $t_{11} = \{hamster, mouse, rabbit, squirrel, spruce, maple, oak, palm, pine, willow\}$, $t_{12} = \{bicycle, bus, motorcycle, pickup truck, train, lane-marking, rocket, satellite, tank, tractor\}$ |

Table 8: Summary of benchmark datasets used in continual learning literature \cite{15, 87, 62, 13} and this work.

The number of images that form a task and the classes in each task for the class-incremental setting are shown.

### G Task-wise Accuracy

Tables 9 through 14 above show task-wise accuracy on the various continual learning datasets used in this work. The average of these accuracy values is presented in Table 1 of the main paper.

The tasks defined on continual versions of CIFAR and ImageNet datasets have implicit semantic meaning. On Split CIFAR-100, there is a significant semantic shift when adding $t_5$, which includes animals (bear, leopard, lion, tiger, wolf) and man-made structures (bridge, castle, house, road, skyscraper). So far the model has been trained on fishes, flowers, fruits and insects. In this challenging setting, MERLIN achieves an improvement of 4.61% in accuracy. Accuracy of GSS and EWC falls while iCaRL and GEM has minor improvement of 1.83% and 1.51%.

In Split CIFAR-10, while adding deer and dog class ($t_5$) to the model that is already trained on bird and cat, the accuracy of all the methods fall, while MERLIN improves the accuracy by 0.25%. We observe an improvement of 2.80% when we add ship and truck as part of $t_5$. The performance of GSS and GEM decreases, while iCaRL, which does well even in Table 1 of the main paper, improves (2.38%) similar to MERLIN. This setting is challenging because the previous three tasks were only animal classes, and there is a semantic shift at $t_5$. The grouping of classes in Split Mini-ImageNet is more or less random. Here, we note that in four out of ten tasks ($t_5, t_7, t_9, t_{10}$), MERLIN achieves better improvement in accuracy when compared to the other methods. On Split CIFAR-100 and Split Mini-ImageNet, GSS degenerates (even after carefully choosing the hyper-parameters) as the number of tasks increase. We note that GSS was not evaluated on these datasets in the original paper.
Wilson and McNaughton, in their seminal paper [84] made the following observation: “...initial storage of event memory occurs through rapid synaptic modification, primarily within the hippocampus. During subsequent slow-wave sleep, synaptic modification within the hippocampus itself is suppressed and the neuronal states encoded within the hippocampus are “played back” as part of a consolidation process by which hippocampal information is gradually transferred to the neocortex.” Further, other work [33 83 75] extended the connection between memory consolidation and improved continual learning capabilities. One can view the phases in our method mirroring the above observation. The base network training (Figure 1 left) is similar to the learning that happens in the hippocampus. After learning a new task, we have a period of inactivity (similar to sleep), where the model weights are encoded, the parameter distribution is re-learned and consolidated by “playing back” model parameters from all learned tasks (Figure 1 middle). Interestingly, many years ago, [64] used auto-associative neural networks [40] to study connections between sleep-induced consolidation and reduction in catastrophic forgetting. Recently, [26] studied the same on a custom build biophysically-realistic thalamocortical network model. The encouraging results from such studies adds further motivation to our proposed methodology.

### Comparison with Bayesian Continual Learning Methods

We compare with a recent bayesian continual learning method, CN-DPM [44], for completeness of our work. We report the results in Table 14. As shown in the table, CN-DPM performs better than MERLIN on Split-MNIST, but drastically fails on harder datasets. We note that the baseline methods considered in this work also perform better than CN-DPM on non-MNIST datasets.
Not all VAE-based continual learning methods learn a posterior over model parameters, or operate in an online continual learning setting. For eg., VCL [55] learns a posterior over the data distribution (also not an online continual learning method), and not model parameter distribution. This is a subtle difference to be noted. MERLIN performs variational continual learning in the model parameter space, can be adapted easily to class and domain incremental setting, and work in task-aware or task-agnostic settings.

J Efficacy of Task-specific Learned Priors

The learned task-specific priors are necessary to generate task-specific weights and consolidate meta-model on previous task parameters, as well as to sample models for ensembling at inference. We ran a study where we replaced the task-specific learned prior with a standard Normal prior and finetuned the corresponding generated model on task-specific exemplars. We showcase the results in Tab [14] where we see that MERLIN fails drastically, validating the usefulness of task-specific learned priors.

K Results on Additional Datasets

Along with the standard continual learning benchmarks that are reported in the main paper, we additionally compare with Heterogeneous dataset introduced by Serra et al. [71]. We also explore continually learning in the audio modality with Audio MNIST dataset [7]. We comfortably outperform baselines on both these datasets too.

L Using Smaller Backbones for the Baselines

MERLIN uses smaller backbones for the non-MNIST experiments. For the results in the main paper, we use larger backbones for the baseline, which is unfair for MERLIN, which still outperforms them. We re-ran all baselines with the same smaller ResNet used in MERLIN, and report the results in Tab [16] We see that MERLIN outperform all baselines here again; the performance of the baseline model drops significantly, possibly due to the smaller capacity.

M 5 class-per-task Experiments

Experiments on CIFAR-100 and Mini-ImageNet datasets in the main paper uses 10 class-per-task. Here we run the incremental experiments with 5 class-per-task. The results are reported in Tab [17] We perform better than baselines even in this setting.

N Code

We share the code for MERLIN here: https://github.com/JosephKJ/merlin
