ABSTRACT

We present the discovery of 130.87 day periodic near-infrared flux variability for the Class II T Tauri star WL 4 (= 2MASS J16271848−2429059, ISO-Oph 128). Our data are from the 2MASS Calibration Point Source Working Database and constitute 1580 observations in J, H, and Ks, of a field in ρ Ophiuchus used to calibrate the 2MASS All-Sky Survey. We identify a light curve for WL 4 with eclipse amplitudes of ~0.4 mag lasting more than one-quarter the period and color variations in J−H and H−Ks of ~0.1 mag. The long period cannot be explained by stellar rotation. We propose that WL 4 is a triple YSO system, with an inner binary orbital period of 130.87 days. We posulate that we are observing each component of the inner binary alternately being eclipsed by a circumbinary disk with respect to our line of sight. This system will be useful in investigating terrestrial-zone YSO disk properties and dynamics at ~1 Myr.

Subject headings: circumstellar matter — stars: pre–main-sequence — stars: variables: other

1. INTRODUCTION

When stars form and contract onto the main sequence, remnant material can remain in a circumstellar disk. More than half of the solar-type young stellar objects (YSOs) possess these primordial disks from which planets can eventually form (Meyer et al. 1997). The physical mechanisms responsible for the evolution and dissipation of primordial disks are not directly observed. ρ Ophiuchus (ρ Oph) is a ~135 pc star-forming region containing several hundred ~1 Myr YSOs (Mamajek 2008; Natta et al. 2006; Barsony et al. 2005; Lada 1987; Lada & Wilking 1984). Photometric variability is a common property of YSOs, and several large-sky and targeted variability studies of YSOs have been undertaken in the near-infrared (near-IR; Alves de Oliveira 2008; Barsony et al. 1997; Carpenter et al. 2001, 2002). With the Two Micron All-Sky Survey (2MASS) Calibration Point Source Working Database (Cal-PSWDB; Skrutskie et al. 2006), we are carrying out a program to study the near-IR variability of YSOs in ρ Oph as a probe of stellar and circumstellar disk evolution. In this Letter, we present the discovery of a YSO with long-term periodic variability that we attribute to eclipses by a circumbinary disk.

WL 4 is a previously unremarkable ~1 Myr Class II T Tauri star in ρ Oph (Natta et al. 2006; Strom et al. 1995). For WL 4, Natta et al. (2006) estimate a J-band extinction of AV = 5.5, an effective stellar temperature of 3715 K, an intrinsic luminosity of 1.2 L⊙, and a mass of 0.45 M⊙. Natta et al. (2006) derive only upper limits for accretion from the Paβ and Brγ emission-line equivalent widths, implying WL 4 is not a strong accretor (log [MW/AVA yr−1]) < −9.1). For comparison, Strom et al. (1995) derived an extinction AV = 5.0 and ~1 Myr mass of 1.4 M⊙ from D’Antona & Mazzitelli (1994) isochrones. Tsuboi et al. (2000) identify three consecutive X-ray flares with a quasi-period of ~20 hr. Ratzka et al. (2005) report a 0.176” companion from high angular resolution imaging, with a projected separation of ~24 AU and a flux density ratio of 0.602 ± 0.062. Observations of WL 4 at infrared and sub-mm wavelengths are presented in § 2.2.

2. OBSERVATIONS

2.1. 2MASS Calibration Observations

2MASS imaged the entire sky in three near-IR bands between 1997 and 2001. Photometric calibration for 2MASS was accomplished using hourly observations of 35 selected calibration fields, with different fields visited each hour. One of these fields in ρ Oph covers a region 8.5’ wide in decl., centered at (R.A., decl.) = (246.80780°, −24.68901°). The calibration fields were observed using the same “freeze-frame” scanning strategy used for the main survey that yielded a net 7.8 s exposure on the sky per scan, with six scans of the field taken in alternating declination directions during each hourly calibration observation. In three ~6 month visibility windows spanning 901 days, 1582 independent scans were made of the field in ρ Oph, including 1580 detections of WL 4. The raw imaging data from each scan of a calibration field were reduced using the same pipeline used to process the main survey. All source extractions from all scans were loaded into the Cal-PSWDB (Cutri et al. 2006). We do not identify the cause of the two missing detections for WL 4 in the Cal-PSWDB, but it is likely an artifact of the automated processing.

2.2. Thermal Infrared and Submillimeter Photometry

The Cores to Disks (c2d) Spitzer Space Telescope Legacy program surveyed star-forming regions including ρ Oph (Evans et al. 2003). The final c2d data delivery (DR4) includes measured flux densities from observations of WL 4 with MIPS with two epochs at 24 μm, one epoch each at 70 and 160 μm (Padgett et al. 2008; Rieke et al. 2004), and two epochs with IRAC at 3.6, 4.5, 5.8, and 8.0 μm (L. Allen et al. 2008, in preparation; Fazio et al. 2004). Padgett et al. (2008) notes that WL 4 and ISO-Oph 129 fall within an elliptical ring of 24 μm emission ~1’ in diameter centered on ISO-Oph 125 and 124. Barsony et al. (2005) observed WL 4 at 10.8 and 12.5 μm. The detection at 12.5 μm appears to be inconsistent with the other measurements. Observations at 70 μm with MIPS and in the sub-mm as reported in Andrews & Williams (2007) and Stanke et al. (2006) are confusion limited by emission from ISO-Oph 124, 125, and 129. In our analysis, we treat such photometry as upper limits.
3. Analysis and Results

3.1. Periodic Variability

For WL 4, periodic variability is apparent in the unphased data, alternating between bright and faint states. We identify a period of 130.87 ± 0.40 days using both the Lomb-Scargle periodogram (Scargle 1982) and the period-searching algorithm of Plavchan et al. (2008). The phased light curve is shown in Figure 1, left. For JD = 2,450,000.0, the corresponding phase in Figure 1, left, is 0.33. We find a peak-to-peak variation of ∼0.4 mag in J, H and K, with a corresponding reddening of ∼0.06 mag in J−H and H−K, when WL 4 is in the bright state. While a ∼65 day period is consistent with the 2MASS results, our best physical model for the system (§ 3.3) requires that this is an alias of the true period. The period is too long to be associated with a 1 Myr YSO stellar rotation period (Rebull 2001).

Superposed on the long-term variability, we identify a second significant period of variability at 4.839 ± 0.015 days (Fig. 1, right). We observe this additional periodic variability in both the faint and bright states, with a larger amplitude in J relative to K. This variability is consistent with rotationally modulated stellar variability (Rebull 2001).

3.2. Spectral Energy Distribution

The c2d IRAC observations of WL 4 were fortunate to coincide with the bright and faint states predicted from the Cal-PSWDB data. We model the spectral energy distribution (SED) in both states. We fit by inspection the photometry with reddened PHOENIX NextGen (Hauschildt et al. 1999) synthetic stellar spectra and a two-temperature blackbody dust model. For both states of WL 4, we are able to reproduce the observations (Fig. 2). We are able to confirm the presence of an infrared excess associated with a primordial disk. We summarize the model parameters in Table 1.

3.3. Model

The long period of the near-IR variability necessitates a binary companion, and the SED indicates the presence a primordial disk. We denote the binary components WL 4a and WL 4b and the companion resolved in Ratzka et al. (2005) as WL 4c. All three components are unresolved with 2MASS and Spitzer. The observed IRAC variability implies a circumbinary disk around WL 4ab, but part of the infrared excess could be associated with a disk around WL 4c. To explain the shape of the light curve, we postulate that a component of the WL 4ab binary goes into obscuration and reemerges from behind a circumbinary disk every 65.44 days. The binary must be inclined with respect to the disk and the disk relatively close to edge-on with respect to our line of sight.

We can solve for the brightnesses of the three components using the total stellar luminosity derived from the SED fit, the magnitude depth of the faint state from one component being obscured, and the flux ratio observed during a predicted bright state in Ratzka et al. (2005). We find that WL 4 is composed of three approximately equal brightness 0.6 $L_\odot$ YSOs. The symmetry between the brightnesses of WL 4a and WL 4b implies that the binary period is 130.87 and not 65.44 days. Our model predicts that WL 4a and WL 4b alternate being obscured by the circumbinary disk. The similar depth and system color during consecutive faint states is consistent with similar spectral types for WL 4a and WL 4b. The color variations occur during the ingress and egress phases of the eclipses, and we do not model this additional complexity. The color changes may indicate a slight difference in spectral types for WL 4a and WL 4b or may be due to varying scattered light...
flux. The estimated stellar masses imply a binary separation of 0.47 AU, or ∼50 stellar radii. Finally, we attribute the 4.84 day periodic variability to stellar rotation modulated starspots on WL 4c, because this is consistent with the variability being observed in both states.

4. DISCUSSION

We list supporting evidence for our model in §§ 4.1–4.3.

4.1. Derived Model Parameters and Lack of Detected Accretion Signatures

The dust luminosities we derive are sufficient to justify the shadowing model, and the variability is detected from 1 to 8 μm. Only two parameters of our model are necessarily varied between the bright and faint states to reproduce the SED: the hot-dust luminosity which is important to reproduce the IRAC channels 2–4 photometry, and the obscuration of one stellar component in the faint state. The change in the hot-dust luminosity indicates possible dynamical interaction or disk “warping,” or simply changing illumination/heating. The hot-dust temperature is consistent with the stable inner orbital radius of ∼2–3 times the binary semimajor axis (Harrington 1977). The presence of WL 4c could account for the dynamical origin of a disk inclined with respect to the orbit of the inner WL 4ab binary.

The lack of a significant component of hot ∼1000 K dust and the lack of strong accretion signatures in Natta et al. (2006) imply the lack of a massive circumprimary disk around WL 4a or 4b. The lack of detected accretion also implies that periodically driven accretion by the companion is not a favored scenario, such as is hypothesized for DQ Tau and AA Tau (Mathieu et al. 1997; Bouvier et al. 2003). Finally, the apparent K∗ magnitude of WL 4 is consistent with a directly visible ρ Oph YSO and is too bright to be an edge-on disk system seen only in scattered light (K. Stapelfeldt et al. 2008, in preparation; Watson & Stapelfeldt 2007; Stapelfeldt et al. 1997).

4.2. Duration of Faint State

A stable circumstellar disk around WL 4a or 4b with an outer radius of one-third the binary separation (Artymowicz & Lubow 1994) would produce an eclipse only ∼10% of the period, so this configuration can be ruled out. Excepting for the ∼4.84 day periodic variability, the light curves in the faint and bright states are relatively flat and smoothly varying for ∼25 and ∼13 days, respectively. The transition between bright and faint states, including the “kinks” in the light curve at phases of 0.14, 0.36, 0.63, and 0.86, last ∼13 days apiece. We speculate that the “kinks” could be due to disk substructure such as a puffed-up or overdense inner edge.

4.3. Similarities to KH-15D

KH-15D is a unique K6–K7 binary YSO in NGC 2264 (Keams & Herbst 1998; Badalian & Erastova 1970). Every ∼48 days, KH-15D periodically varies in brightness by ∼4 mag between relatively quiescent bright and faint states. An inclined binary with a ∼48 day period surrounded by a nearly edge-on circumbinary disk is invoked to explain these observations, as the primary component of KH-15D periodically “peeks out” from behind the disk (Winn et al. 2006; Johnson et al. 2005; Winn et al. 2004; Chiang & Murray-Clay 2004; Johnson & Winn 2004; Winn et al. 2003). The near-IR photometry and colors vary in tandem in a similar fashion for both KH-15D and WL 4, although the amplitude differs. When both sources get brighter, both sources also get redder in J − H and H − K, (Kusakabe et al. 2005). Kusakabe et al. (2005) attribute the
reddening for KH-15D to changes in the scattered light flux. Similar features such as the “kinks” in the light curve in Figure 1, left, have also evolved with time for KH-15D.

5. CONCLUSIONS AND FUTURE WORK

We have identified periodic variability for the YSO WL 4 in ρ Oph that is likely due to alternating eclipses of two different components of a binary system by a circumbinary disk. The faint state lasts longer than the bright state, ruling out a coplanar stable circumpinary disk to explain the observations. WL 4 is a unique and valuable probe of YSO terrestrial-zone disk evolution. We want to confirm our binary model for the light-curve modulation. The radial velocity amplitude implied by our model should be measurable through high-resolution near-IR spectroscopy with adaptive optics. Detailed modeling of the disk with orbital dynamics of the binary is warranted to reproduce the observed light curves, including the “kinks,” and to investigate the dynamical stability of our model. Near- and mid-IR photometric and spectroscopic observations will enable a characterization of the dust grain properties and disk structure.

This publication makes extensive use of data products from 2MASS, which is a joint project of the University of Massachusetts and IPAC/California Institute of Technology, funded by NASA and NSF. This research has made use of the NASA/IPAC Infrared Science Archive, which is operated by Jet Propulsion Laboratory, California Institute of Technology, under contract with NASA. Thanks to Mike Meyer, Mike Werner, Angelle Tanner, and Eric Agol for their conversations and comments. Parts of the research described in this publication were carried out at JPL.
