Abstract

**Background:** Lactic acid bacteria (LAB) are applied worldwide in the production of a variety of fermented food products. Additionally, specific *Lactobacillus* species are nowadays recognized for their health-promoting effects on the consumer. To optimally exert such beneficial effects, it is considered of great importance that these probiotic bacteria reach their target sites in the gut alive.

**Methodology/Principal Findings:** In the accompanying manuscript by Bron et al. the probiotic model organism *Lactobacillus plantarum* WCFS1 was cultured under different fermentation conditions, which was complemented by the determination of the corresponding molecular responses by full-genome transcriptome analyses. Here, the gastrointestinal (GI) survival of the cultures produced was assessed in an *in vitro* assay. Variations in fermentation conditions led to dramatic differences in GI-tract survival (up to 7-log) and high robustness could be associated with low salt and low pH during the fermentations. Moreover, random forest correlation analyses allowed the identification of specific transcripts associated with robustness. Subsequently, the corresponding genes were targeted by genetic engineering, aiming to enhance robustness, which could be achieved for 3 of the genes that negatively correlated with robustness and where deletion derivatives displayed enhanced survival compared to the parental strain. Specifically, a role in GI-tract survival could be confirmed for the *lp_1669*-encoded AraC-family transcription regulator, involved in capsular polysaccharide remodeling, the penicillin-binding protein Pbp2A involved in peptidoglycan biosynthesis, and the Na+/H+ antiporter NapA3. Moreover, additional physiological analysis established a role for Pbp2A and NapA3 in bile salt and salt tolerance, respectively.

**Conclusion:** Transcriptome trait matching enabled the identification of biomarkers for bacterial (gut-)robustness, which is important for our molecular understanding of GI-tract survival and could facilitate the design of culture conditions aimed to enhance probiotic culture robustness.

Introduction

According to the world health organization (WHO) probiotics are defined as live microorganisms which, when administered in adequate amounts, confer a health benefit on the host [1]. The most widely applied probiotic strains belong to the genera *Lactobacillus* and *Bifidobacterium* [2,3]. Probiotics are most commonly provided as freshly fermented food products, non-fermented food products to which probiotics are added, or as dried bacterial preparations [3,4]. The viability of bacteria is considered an important trait for probiotic functionality, justifying the interest to unravel the mechanism(s) involved in gastrointestinal (GI)-tract survival at the molecular level [5,6,7,8].

During passage through the GI-tract, probiotics encounter several stresses including acidity in the stomach which may reach a pH as low as 1 during fasting [7]. This low extracellular pH affects the proton motive force of the bacterial cells, thereby disrupting the energy supply required for processes such as

membrane transport [9]. In addition, lower intracellular pH values caused by acidic conditions may inhibit specific pathways by damaging acid-sensitive associated enzyme functions [9]. After stomach passage probiotic strains reach the small intestine, where bile acids act primarily as a surfactant that can disrupt bacterial membranes [10] and damage macromolecules such as RNA and DNA through the generation of free oxygen radicals [11]. Moreover, protonated bile acids can freely pass bacterial cell membranes and release protons intracellularly which might lead to lowering of the intracellular pH, analogous to acid stress [9].

Among the lactobacilli, *Lactobacillus plantarum* is encountered in a plethora of fermentsations, ranging from vegetables to dairy, meat and sourdough [12,13]. *L. plantarum* is also frequently encountered as a natural inhabitant of the GI-tract of several mammals, including humans [14]. In addition, *L. plantarum* NCIMB8826 was demonstrated to effectively survive passage of the human stomach, reached the ileum in high numbers, and was detected in the colon [15]. A single colony isolate of this strain (designated *L. plantarum* strain WCFS1) was the first *Lactobacillus* strain of which the full genome sequence was published [16]. Subsequently, sophisticated bioinformatics tools were developed for this LAB strain, including an advanced genome annotation [17], genome-based metabolic models [18], as well as effective mutagenesis tools [19]. This enables the molecular investigation of gene-regulatory mechanisms underlying the observed GI-tract persistence of *L. plantarum* WCFS1.

The availability of full genome sequences has also enabled the exploration of genomic diversity among *L. plantarum* strains and its association to differential phenotypes [13,20,21,22,23]. To enable the identification of genes of which the relative expression level is correlated to the phenotype of interest, we recently developed a complementary transcriptome-phenotype matching strategy for *L. plantarum* (see accompanying paper by Bron et al.). Here, we employed this fermentation genomics platform to correlate transcriptome data to GI-tract survival. These correlations led to the identification of 13 candidate effector molecules for GI-tract persistence. A subsequent gene deletion strategy established a definitive role in GI-tract persistence for the AraC-family transcription regulator encoded by *lp_1669*, the penicillin-binding protein Pbp2A involved in peptidoglycan biosynthesis, and the Na⁺/H⁺ antiporter NapA3.

**Results**

**Gastric Acidity is a Critical Determinant of *L. plantarum* Survival**

An *in vitro* assay was developed that allows high-throughput assessment of bacterial GI-tract survival (fig 1A). Two independent reference *L. plantarum* WCFS1 cultures that were harvested during logarithmic phase of growth (OD$$_{600}$$=1.0) displayed a 6-log decrease in CFU ml$$^{-1}$$ in the GI-tract assay (fig 1B). The survival curves of these reference cultures demonstrated the major impact on survival exerted by gastric juice on *L. plantarum* viability and the relatively minor effect of the conditions which resembled the small intestine (fig 1B). This differential effect on survival during the two stages within the GI-tract assay was consistently observed for all cultures tested, irrespective of the fermentation conditions applied or the growth phases from which bacterial cells were harvested.

The strongest determinant in the loss of survival during the gastric juice treatment appeared to be pH. For screening log-phase cells of *L. plantarum*, a pH of 2.4 was used for cells, as lowering or increasing of the gastric juice pH by 0.1 pH unit resulted in death or survival of almost all cells, respectively (over 7-log differences, data not shown). *L. plantarum* cells harvested at the stationary phase of growth consistently displayed a higher tolerance to the gastric juice treatment, which is exemplified by their higher survival rate in the GI-tract assay when a reduced pH of 2.3 was used (fig 1B) at which the cells harvested from the logarithmic phase of growth were nearly all killed within 60 minutes of incubation.

**Fermentation-enhanced Digestive Tract Survival**

We examined the effects of different growth conditions on *L. plantarum* WCFS1 GI-tract survival by applying samples derived from the fermentation-genomics platform described in the accompanying paper by Bron et al. to our *in vitro* GI-tract assay. The results demonstrate that fermentation conditions used to culture *L. plantarum* WCFS1 conferred a profound influence on the GI-tract survival. Variable fermentation conditions resulted in major differences (a reduction of 7 logs for the logarithmic population and 5 logs for stationary cells) in *L. plantarum* WCFS1 survival after incubation in gastric juice (fig 2). Notably, survival of cultures grown in different fermentation conditions strongly exceeded the levels of variation in survival observed in independent GI-tract assays (fig 1B).

To identify the fermentation conditions that significantly affected the survival rate in the simulated GI-tract conditions, a
Mann-Whitney U test-based correlation analysis was performed in FermDB on all time points measured (See accompanying manuscript by Bron et al. for correlation analyses details). The presence of 300 mM additional NaCl in the growth medium resulted in a significant ($P<0.05$) negative influence on *L. plantarum* GI-tract survival irrespective whether cells were analyzed after collection from either logarithmic or stationary phase of growth (shown for 60 min incubation in fig. 3A and B). *L. plantarum* grown

Figure 2. Relative GI-tract survival of differently grown *L. plantarum* WCFS1. \( \log_{10} \text{CFU ml}^{-1} \) determination of *L. plantarum* WCFS1 in logarithmic phase (A) and stationary phase (B) after 20 (light grey), 40 (dark grey), and 60 min (black) gastric juice incubation. Input is set at \( \log_{10} \text{CFU ml}^{-1} \), \# = fermentation number, cultures were grown in \( 2 \times \text{CDM} \) with (300 mM) or without (0) NaCl; with normal amino acid concentration (2) or reduced (1.1); at 28 \( ^{\circ} \text{C} \) or 37 \( ^{\circ} \text{C} \); medium buffered at a pH of 5.2, 5.8, or 6.4; and aerobically (\( \text{O}_2 \)) or anaerobically (\( \text{N}_2 \)). Data presented are averages of technical sextuplicates (+ standard deviation).

Mann-Whitney U test-based correlation analysis was performed in FermDB on all time points measured (See accompanying manuscript by Bron et al. for correlation analyses details). The presence of 300 mM additional NaCl in the growth medium resulted in a significant ($P<0.05$) negative influence on *L. plantarum* GI-tract survival irrespective whether cells were analyzed after collection from either logarithmic or stationary phase of growth (shown for 60 min incubation in fig. 3A and B). *L. plantarum* grown
in more acidic conditions (pH 5.2 instead of pH 6.4) and harvested in stationary phase showed a significantly ($P < 0.05$) enhanced the gastric juice survival rate (shown for 60 min in fig. 3C).

Transcriptome to Phenotype Association Identifies Candidate Effector Molecules for GI-tract Survival

In parallel with the GI-tract survival patterns, transcriptome profiles were obtained for logarithmic cells harvested from all fermentation conditions employed in this study (see accompanying paper by Bron et al.). To investigate whether high- and low-rate surviving cultures in the GI-tract assay could be distinguished based on the expression of specific genes, the cultures were first ranked on their GI-tract survival after gastric juice incubation ($t = 60$ min). For cultures that had retained undetectable survival rates after 60 min of gastric incubation, the relative survival rates after 20 min and 40 min of gastric incubation, were employed to refine their relative survival ranking (fig. 2A).

The transcriptomes of the eight cultures with the highest survival rates and the eight cultures with the lowest survival in the GI-tract assay were clearly distinguishable according to principal component analysis (PCA) (fig. 4). This result indicated that the transcriptomes contained information (genes) within the first two components of the PCA which might allow the discrimination between high- and low-survival rates in the GI-tract assay. To identify specific transcripts that discriminate between high and low GI-tract survival, and thus can be regarded as candidate robustness markers, the random forest algorithm was applied (see the accompanying paper by Bron et al.). This allowed the identification of transcripts that have a high contribution to accurately predict the low- and high-survival outcomes (table S1).

Validation of Target GI-tract Survival Effector Molecules by Mutagenesis

To validate the association of the expression level of specific genes in *L. plantarum* with GI-tract survival, the 13 genes with the highest ranking based on the criteria described in the Materials and Methods section were targeted by genetic engineering (table 1), aiming to improve GI-tract survival beyond the levels observed with the wild-type strain. Therefore, the direction of the
correlation between transcript intensity and survival in the GI-tract assay determined whether a gene would be targeted for overexpression (positive correlation, see fig. 5A for an example) or gene-deletion (negative correlation, fig. 5B).

Genes targeted for sakacin-inducible overexpression were thrC, lp_0149, hicD3, and lp_1357 (table 1). For folB overexpression, we used a previously constructed mutant that overexpresses the entire folB-folK-folE-folC2-xtp2-foIP cluster [24,25]. Sakacin P induced overexpression of the cytoplasmic hicD3 and thrC and the downstream lp_2759 gene products could readily be confirmed by SDS-PAGE analysis of cell-free extracts of induced cultures (figure S1). In contrast, overproduction of the membrane-anchored lp_1357 and transmembrane proteins (lp_0148–0150) were not distinguishable by SDS-PAGE (data not shown). Although overexpression could only be demonstrated for two of the genetic loci, we applied all overexpression strains to our GI-tract assay. The constructed overexpression and gene deletion mutants were grown until the logarithmic growth phase and subjected to the GI-tract assay. The survival of the Sakacin P induced overexpression mutants was anticipated to improve when compared to a control strain harboring the empty induction plasmid (fig. 6). Although not significant, the contrary seemed to be the case, since the slight effects that were observed in some of the experiments suggested that the expression of the cloned genes reduced the survival capacity of these cells rather than improved.

In contrast, the L. plantarum Δphp2A::cat, Δlp_1669::cat, and ΔnapA3::cat mutants showed significantly improved survival in the GI-tract assay, as compared to their parental strain (fig. 7). These strains harbored disruptions in genes associated with poor survival in gastric stress. Notably, we have combined the individual mutants described here to construct Δphp2A::ΔnapA3::cat and ΔnapA3::Δlp_1669::cat. However, these double gene deletion derivatives displayed robustness phenotypes comparable to the single ΔnapA3::cat gene deletion derivative, indicating that the positive effect on GI robustness of these mutations appeared not cumulative (data not shown). Nevertheless, these results establish the involvement of certain fermentation-condition dependent gene products in GI survival.

Php2A is annotated as a penicillin-binding protein involved in peptidoglycan biosynthesis, Lp_1669 is predicted to be a transcription regulator, and NapA3 is homologous to Na+/H+ antiporters. To gain more insight in the mechanisms by which these proteins influence robustness, growth of the parental strain and the Δphp2A::cat, Δlp_1669::cat, and ΔnapA3::cat derivatives was monitored under standard- and stress-conditions. At 28°C in complex culture medium (MRS), the growth rates of the mutants did not differ from the wild-type, nor did the addition of H₂O₂ (1 to 5 mM), lysozyme (0.025 to 3.2 g/ml), or SDS (0.9 to 30 g/l) induce differences in growth rate of the mutants compared with the wild type strain. However, the presence of bile salts (10 to

50 mM) in the culture medium reduced the maximum growth rate of \( \text{Dpbp2A::cat} \) to 20% as compared to the parental strain (data not shown). This result indicates that Pbp2A contributes to the survival capacity of \( L. \text{plantarum} \) in low-pH, stomach like conditions, but also improves bile tolerance, but not to tolerance to detergents in general.

The addition of NaCl to the growth medium reduced the growth rate of \( \text{DnapA3::cat} \) to 20% (400 mM) and 80% (1 M) of the wild type (data not shown). As NapA3 is a \( \text{Na}^+/\text{H}^+ \) antiporter which might be affected by extracellular pH, the growth of the \( \text{DnapA3::cat} \) mutant was monitored under different starting pH conditions (pH 4.6 to 6.4) in the presence and absence of NaCl (300 mM). The growth rate of the mutant appeared unaltered during growth in the absence of salt. Only the presence of NaCl reduced the growth rate of \( \text{DnapA3::cat} \) under all measured conditions (data not shown). These results support a role of this function in salt tolerance, which in our experiments, appeared to be independent of the pH.

Contrary to \( \text{DnapA3::cat} \) and \( \text{Dpbp2A::cat} \), a specific phenotype was not established for the transcription regulator \( \text{Lp}_1669 \). To elucidate the regulon associated with this regulator, the transcriptome profile of the \( \text{NZ3417CM (Dlp}_1669::\text{cat}) \) strain was compared to that of the wild-type strain grown in 2 \( \times \) CDM [17] or MRS. The results showed that the \( \text{Lp}_1669 \)-deficient strain displayed enhanced expression of genes belonging to the main functional class of cell envelope associated functions, and more specifically to its subclass of surface polysaccharides, lipopolysaccharides, and antigens. This effect of the mutation was observed independent of the medium used (fig. 8 and table S2 and S3). Analysis at the individual transcript level revealed that the capsular polysaccharide (CPS) clusters \( \text{eps2, eps3,} \) and \( \text{eps4} \) were induced in the MRS-grown \( \text{Lp}_1669 \)-deficient strain as compared to the wildtype, suggesting that the regulatory function

encoded by \(lp_\text{1669}\) is involved, either directly or indirectly, in the regulation of CPS biosynthesis. Notably, especially the expression of the \(cps2\) cluster was induced in \(2 \times \text{CDM}\) grown \(Lp_\text{1669}\) deficient cells (table S2 and S3). Analysis of monosaccharide composition revealed minor changes in CPS sugar composition of the \(Lp_\text{1669}\)-deficient strain in comparison to the wild type strain (table 2). Galactosamine was only detected in the mutant strain, whereas arabinose was found only in the wild-type strain. Rhamnose and glucosamine also tended to be slightly more abundant in the wild type \(L. \text{plantarum} \) WCFS1. Moreover, the average molar mass of \(\Delta lp_\text{1669}\):cat strain-derived CPS was 1.5-fold higher compared to the wild type (Table 2). This indicates that \(Lp_\text{1669}\) seems to be involved in subtle CPS modification, specifically in chain length determination. These observations might also (partially) explain the observed increased gastrointestinal survival of the \(L. \text{plantarum} \) \(Lp_\text{l669}\)-deficient strain.

Discussion

This study demonstrates that the production method, medium composition, and stage of growth strongly influenced the GI-survival efficacy of \(L. \text{plantarum} \) WCFS1. Combining the fermentation and survival data pinpointed to specific fermentation conditions that may enhance robustness (low salt and low pH), whereas genome association analysis of the transcriptome and survival data revealed 13 genes potentially involved in GI-survival.

As reported previously [26], cells harvested from stationary phase generally were more robust than logarithmically growing cells, and in particular, those cells displayed enhanced survival in gastric juice which overall had a dramatically larger impact on survival compared to pancreatic juice. The influence of acidity on GI-tract survival was also emphasized by the observation that lowering the gastric juice pH by as little as 0.1 unit had a pronounced impact on survival. Differences among bacterial
species in their sensitivity to gastric and intestinal secretions have been observed before [27,28,29] and a higher sensitivity for acid than bile stress was also noted for <i>L. rhamnosus</i>, as well as for other <i>L. plantarum</i> strains [30,31]. The finding that exposure to low pH during growth enhances GI-survival is in agreement with earlier observations that pre-adaptation to sublethal stress conditions enhances the subsequent robustness of bacteria to lethal stress conditions [9], supporting the suitability of the fermentation genomics platform and bioinformatics tools employed in this study and the accompanying paper by Bron et al. For salt it is known that it can protect against, but also increase susceptibility to, other stresses [32,33]. Moreover, these results clearly establish that fermentation conditions have a major impact on the GI-tract associated stress tolerance of bacterial cultures, and that specifically mild salt stress and lower pH adaptation may elicit adaptive responses that reduce and support such stress tolerance, respectively.

Overexpression and gene deletion derivatives of the parental strain were constructed, depending on the direction of the predicted correlation to GI-tract survival and aiming to enhance this trait. Three of the five constructed gene deletion derivatives displayed enhanced GI-tract survival, confirming the predicted role of the targeted genes. By contrast, none of the overexpression derivatives displayed improved robustness behavior in the GI-tract assay, and all had survival characteristics that were virtually identical to those of the parental strain. A possible explanation for these observations may be found in the potential disruption of a gene-regulatory network by the deletion of a single gene in that network, while overexpression of a single element from a complementary gene-function network may not provide the same effect as the enhanced expression of all elements in the network. The fact that 3 out of 5 gene deletion derivatives displayed enhanced survival is in line with earlier observations [21,22,23] and can be explained by the fact that the random forest algorithm also leads to the identification of non-causal relationships, reiterating the importance of follow-up mutagenesis approaches to establish a definite role for candidate biomarkers identified with this algorithm.

The 3 genes for which the importance in GI-tract survival could be confirmed by gene deletion encode a AraC family regulator (Lp_1669), a Na⁺/H⁺ antiporter; NapA3, and a penicillin binding protein; Pbp2A. Notably, all three proteins are associated with cell wall modification and transport, and their mutation may lead to cell envelope modulation. This finding per se, may not be qualified as surprising, because the cell envelope is the first line of defense against stresses [34]. Moreover, the resistance to acid and adaptation to bile stress in <i>L. plantarum</i> WCFS1 has been associated with membrane integrity and cell envelope modifications, respectively [35,36]. The AraC family of regulators to which Lp_1669 belongs [16] is characterized by transcriptional regulators that act mostly as activators. However, in some cases these regulators serve as repressors of transcription or as both activators and repressors [37]. The observed effect of Lp_1669 on GI-tract survival is likely to be indirect, possibly via CPS remodeling, because the Lp_1669-deficient strain had CPS with a higher molar mass that might result in a thicker CPS layer around the cells. It has been demonstrated that the presence of EPS/CPS improved the <i>in vivo</i> GI survival of <i>L. rhamnosus</i> GG [38]. The Na⁺/H⁺ antiporter NapA3 might affect GI survival via a role in pH homeostasis. Because disruption of napA3 improved GI-tract survival, it seems likely that NapA3 exports sodium ions associated with the influx of protons, thereby decreasing its internal pH and proton motive force due to the acid stomach conditions. This is also in line with our observation that the gene deletion derivative is only reduced during growth in the presence of sodium salts. Finally, <i>pbp2A</i> encodes the penicillin binding protein 2A which is annotated to be involved in peptidoglycan biosynthesis [16]. Disruption of <i>pbp2A</i> improved the acid stomach condition survival, while it decreased the growth rate in the presence of bile. Noteworthy in this respect is the finding that the compositions of peptidoglycan directly affects the integrity of the cells and can influence the acid- and bile-tolerance [9,39,40,41]. Moreover, transcriptome analysis of <i>L. acidophilus</i> NCFM and <i>L. plantarum</i> WCFS1 demonstrated that many genes related to cell membrane and peptidoglycan biosynthesis displayed altered expression profiles during exposure to bile [39,42]. An increased acid sensitivity by the inactivation of penicillin binding proteins is found in <i>Lactobacillus lactis</i> and <i>L. ruminis</i> [9,40]. However, we found the deletion of <i>pbp2A</i> improves the GI-tract survival, which suggests that disruptions in peptidoglycan biosynthesis genes could either improve or decrease the survival of probiotics, reiterating the general concept of subtle inter-strain and species differences in survival mechanisms.

In conclusion, this study demonstrated that fermentation conditions have a large influence on the GI-tract survival of <i>L. plantarum</i>. We showed that transcriptome-trait matching enables the identification of genetic loci involved in gastrointestinal robustness and this approach can also be employed to rationally design fermentation and process conditions that aim for the production of probiotics with improved GI survival and consequently have a higher potential to achieve their desired health-beneficial effects on the consumer.

**Materials and Methods**

**GI-tract Assay and Correlation to Transcriptome Data**

Cells were harvested from the fermentation-genomics platform at OD₆₀₀ = 1.0 for full-genome transcriptome profiling (see accompanying paper by Bron et al.), while the GI-tract survival was determined in the same cells, as well as in cells that were harvested 25 h after inoculation. One set of fermentations (F19–F24, see accompanying paper by Bron et al.) was excluded from the data analysis as the GI-tract survival data appeared unreliable, likely caused by minor deviations in the pH of the batch of GI applied which is known to heavily influence GI survival. For GI-tract survival analysis, cultures were washed with prewarmed (37°C) PBS and resuspended in prewarmed (37°C) filter sterilized gastric juice [53 mM NaCl, 15 mM KCl, 1.3 mM CaCl₂, 6.2 mM MgCl₂, 6.1 mM Na₂HPO₄, 0.6 mM KH₂PO₄, glucose 26.7 mM, 0.04 M HCl].
5 mM Na₂CO₃, 1 mM CaCl₂, 0.1 mg ml⁻¹ lipase (Fluka; derived from Aspergillus niger), and 1.2 mg ml⁻¹ pepsin (Sigma; derived from porcine) that had a pH adjusted to 2.4 with HCl (logarithmic cells) or 2.5 (stationary cells). The gastric juice enzymes were added immediately prior to the treatment. After 60 min incubation while rotating at 10 rpm in a Hybridization oven/shaker (Amersham pharmacia biotech, Little Chalfont, UK) at 37°C, the cultures were neutralized to pH 6.5 with 0.5 M NaHCO₃, and prewarmed (37°C) pancreatic juice [85 mM NaCl, 5 mM K₂HPO₄, 2 mM Na₂HPO₄, 10 mM NaHCO₃, 30 mg ml⁻¹ pancreatin (Sigma; derived from porcine stomach) and bile acid mixture (latter two components were added fresh to pancreatic juice immediately prior to the treatment)] was added, followed by continued incubation for another 60 min (agitation at 10 rpm, 37°C). The bile acid mixture consisted of 3.0 mM (final concentration in assay) sodium glycocholate hydrate, 1.3 mM sodium glycodeoxycholate, 2.4 mM sodium glycochenodeoxycholate, 1.0 mM taurocholic acid sodium salt hydrate, 0.4 mM sodium taurochenodeoxycholate and 1.0 mM sodium taurochenodeoxycholate to mimic human bile components and concentrations [43]. Preceding and during GI-tract assay incubation (t = 0, 20, 40, 60, 90, and 120), samples were taken for colony forming unit (CFU) enumeration by spot-plating [44]. A reduction of 8 logs could be detected with this method. Relative GI-tract survival of the different cultures was expressed as the fraction of the surviving number of viable cells (t = 0 was set at 1.00). The transcriptome and GI-tract survival data are available in FermDB (www.cmbi.ru.nl/fermdb).

The initial list of genes predicted by the random forest algorithm [45] (see the accompanying paper by Bron et al. for details on correlation analyses) to be associated with GI-tract survival was further refined by application of several selection criteria that are based on transcript ranking. Firstly, only transcripts with an importance factor higher than 1 according to the random forest algorithm were selected for further analysis. Secondly, the quantitative correlation of individual transcripts with the survival rate observed in individual cultures was evaluated, and their associated genes (table 1) were considered to have the strongest correlation with the measured gastric juice tolerance and survival was further refined by application of several selection criteria that are based on transcript ranking. Firstly, only transcripts with an importance factor higher than 1 according to the random forest algorithm [45] (see the accompanying paper by Bron et al. for details on correlation analyses) to be associated with GI-tract survival was further refined by application of several selection criteria that are based on transcript ranking. Secondly, the quantitative correlation of individual transcripts with the measured gastric juice tolerance and...
then incubated at 37°C. After OD_{600} had reached 0.3, the inducing peptide was added to the cultures at varying concentrations of 0, 0.1, 1, 10, and 50 ng/ml. Incubation was continued at 37°C for another 4 h until the OD_{600} had reached approximately 1.8. Bacterial cells were collected by centrifugation at 5,200 g for 10 min, followed by resuspension of the cell pellet in 50 mM Sodium-phosphate buffer pH 7. The cells were disrupted with 1 g zirconium beads by using a FastPrepTM (Thermo Scientific, USA) for 4 cycles of 30 s at 5,200 g. DNA Microarray Analysis and Data Visualization

DNA microarray analysis was performed to compare global transcriptome profiles of NZ3417CM (Δlp_1669::cat) and the wild-type. RNA isolation from *L. plantarum* NCIMB8826 and the wild-type was performed as described above. cDNA synthesis was performed using the Superscript III First-Strand Synthesis System (Invitrogen, Carlsbad, CA, USA). cDNA synthesis was performed using Poly(A) RNA from each sample and the MMLV reverse transcriptase (Invitrogen). cDNA was fragmented and used for hybridization to DNA microarrays containing 60-mer DNA sequences representing 3,968 genes (Qiagen Inc, Cudex, France). After the disruption, the samples were centrifuged 5 min at 20,800 x g to obtain cell-free extracts for analysis by SDS-PAGE.

### Table 3. Strains and plasmids used in this study.

| Strain or plasmid | Relevant feature(s)* | Reference |
|-------------------|----------------------|-----------|
| **Strains**       |                      |           |
| *L. plantarum*    |                      |           |
| WCFS1             | Single-colony isolate of *L. plantarum* NCIMB8826 | [16]      |
| NZ3412^CM         | Derivative of WCFS1 containing a lex6-P32-cat-lox71 replacement of pbp2A (Δlpbp2A:cat) | This work |
| NZ3412            | Derivative of WCFS1 containing a lex72 replacement of pbp2A (Δlpbp2A) | This work |
| NZ3417^CM         | Derivative of WCFS1 containing a lex6-P32-cat-lox71 replacement of lp_1669 (Δlp_1669:cat) | This work |
| NZ3414^CM         | Derivative of WCFS1 containing a lex6-P32-cat-lox71 replacement of lp_1817 (Δlp_1817:cat) | This work |
| NZ3415^CM         | Derivative of WCFS1 containing a lex6-P32-cat-lox71 replacement of pacL3 (ΔpacL3:cat) | This work |
| NZ3416^CM         | Derivative of WCFS1 containing a lex6-P32-cat-lox71 replacement of napA3 (ΔnapA3:cat) | This work |
| NZ3416            | Derivative of WCFS1 containing a lex72 replacement of napA3 (ΔnapA3) | This work |

*Str*, streptomycin resistant; Cm^r^, chloramphenicol resistant; Em^r^, erythromycin resistant.

doi:10.1371/journal.pone.0039053.t003

(Thermo Scientific, USA) for 4 cycles of 30 s at 5,200 g. DNA microarray analysis was performed to compare global transcriptome profiles of NZ3417CM (Δlp_1669:cat) and the wild-type. RNA isolation from *L. plantarum*, subsequent cDNA synthesis
and indirect labeling, as well as DNA microarray hybridizations were performed as described in the accompanying paper by Bron et al. The hybridization scheme is presented in figure S3. Genes of the Lp_1669 regulon with FDR-adjusted p-values less than 0.05 together with a fold-change higher than 2.0 or lower than 0.5 were considered to be significantly differently expressed. All microarray data is MIAME compliant and is available in the GEO database under accession number GSE31254. The biomolecular interaction network of the Lp_1669 regulon in 2× CDM and MRS was visualised using the Cytoscape software (version 2.8.1) [51], and the Biological Networks Gene Ontology (BiNGO) tool [52] was employed to detect significantly overrepresented categories in the regulon of Lp_1669. See the accompanying paper by Bron et al. for details.

**Phenotypic Assays of Mutant Strains**

Gene deletion mutants were analyzed for their gastrointestinal survival characteristics in a procedure identical to that described for the wild-type (see above). To evaluate the relative GI-tract survival of the overexpression mutants, the mutant strain SJP411B (empty vector) and the overexpression mutants were sakacin-induced (50 ng/ml) (see above). Additionally, to measure the relative GI-tract survival of the folate overexpression strain, strains NZ7021 (empty vector) and NZ7026 (folate overproducing strain) [25] were inoculated at OD600 = 0.1 in MRS containing 80 mg/ml chloramphenicol and 0 or 10 mg/ml p-aminobenzoic acid (pABA) according to Wegkamp et al. [24], grown at 37°C until OD600 was 1.0, and subjected to the GI-tract survival assay. To evaluate relative growth efficiency of the deletion mutants, the parental strain (WCFS1) and mutant strains NZ3412CM (Δlp_1669::cat), NZ3416CM (Δlp_2759::cat), NZ3417CM (Δlp_1579::cat), and NZ3418CM (Δlp_1669+lp_1579::cat) were inoculated at OD600 = 0.1 in 96-wells plates and incubated in MRS broth at 28°C. OD600 of the cultures was monitored spectrophotometrically using the Cytoscape software (version 2.8.1) [51], and visualised using the Cytoscape software (version 2.8.1) [51], and quantitative analysis was done with a linear gradient to 200 mM sodium hydroxide with a fixed temperature of 35°C (ERC-5000, Erma Optical Works, Tokyo, Japan).

**Capsular Polysaccharide Isolation and Determination**

Capsular polysaccharide (CPS) was purified and chain lengths and sugar composition were determined essentially as described before [53]. Briefly, 500 ml cultures of L. plantarum WCFS1 and NZ3417CM (Δlp_1669::cat) were grown in 2× CDM at 37°C until stationary phase (25 h). After 1 h incubation at 55°C, the cells were separated from the CPS containing growth medium by centrifugation for 15 min (6000×g) and to prevent overgrowth during dialysis, erythromycin was added to the supernatant to a final concentration of 10 μg/ml. A dialyzing tube 12–1400 Da (Fisher Scientific) was prepared by boiling twice 2% NaHCO3/2 mM EDTA, and once in reverse osmosis water. After overnight dialysis against running tap water followed by 4 h dialysis using reverse osmosis water, the samples were freeze-dried and stored at −20°C until further analysis. The samples were dissolved in eluent (100 mM NaNO3+0.02% NaN3), filtered over 0.2 μm, and placed in a thermally controlled sample holder at 10°C and 200 μl was injected (model 231 Bio, Gilson) on the columns connected in series and remained at 35°C with a temperature control module (Waters, Milford, USA) to perform size exclusion chromatography (SEC) [TSK gel PWXL guard column, 6.0 mm ×4.0 cm, TSK gel G6000 PWXL analytical column, 7.8 mm ×30 cm, 15.0 μm and TSK gel G5000 PWXL analytical column, 7.8 mm ×30 cm, 10 μm (TosoHaas, King of Prusis, USA)].

Light scattering was measured at 632.8 nm at 15 angles between 32° and 144° (DAWN DSP-F, Wyatt Technologies, Santa Barbara, USA). UV absorption was measured at 280 nm (CD-1595, Jasco, de Meern, The Netherlands) to detect proteins. The specific viscosity was measured with a viscosity detector (ViscoStar, Wyatt Technologies, Santa Barbara, USA) at 35°C and sample concentration was measured by refractive index detection, held at a fixed temperature of 35°C (ERC-7510, Erma Optical Works, Tokyo, Japan).

During the analysis with SEC the polysaccharide peak was collected (2 min ×0.5 mL/min = 1 mL). The acid hydrolysates of the collected polysaccharide were carried out for 75 min at 120°C with 2 M trifluoro acetic acid under nitrogen. Following hydrolysates, the solutions were dried overnight under vacuum and dissolved in water. High Performance Anion Exchange Chromatography with Pulsed Amperometric Detection (HPAEC-PAD) on a gold electrode was used for the quantitative analyses of the monosaccharides rhamnose, galactosamine, arabinose, glucosamine, galactose, glucose, mannose, xylose, galacturonic acid, and glucuronic acid. The analyses were performed with a 600E System controller pump (Waters, Milford, USA) with a helium degassing unit and a model 40 EC detector (EG&G, Albuquerque, USA). With a 717 autosampler (Waters, Milford, USA), 20 μl of the sample was injected on a Dionex CarboPac PA-1, 250×4 mm (10–32), column thermostated at 30°C. The monosaccharides were eluted at a flow rate of 1.0 mL/min. The monosaccharides were eluted isocratic with 16 mM sodium hydroxide, followed by the elution of the acid monosaccharides starting at 20 min with a linear gradient to 200 mM sodium hydroxide +500 mM sodium acetate in 20 minutes. Data analysis was done with Dionex Chromeleon software version 6.80. Quantitative analyses were carried out using standard solutions of the monosaccharides (Sigma-Aldrich, St. Louis, USA).

**Supporting Information**

**Figure S1** SDS-PAGE of cell-free extracts logarithmic L. plantarum strains overexpressing hicD3 (lp_2349) and overexpressing thrC (lp_2758) and lp_2759. The arrows indicate protein bands increasing with increasing amounts of Sakacin P (inducing peptide, IP). Empty vector = pSI1P411B. L. plantarum harboring pNZ3431 (over-hicD3), and pNZ3432 (over-thrC+lp_2759). Marker sizes are indicated in kDalton (kDa).

**Figure S2** Cytoscape version of figure 8; regulatory network of Lp_1669 grown in 2× CDM or MRS. Yellow rectangle nodes represent growth in 2× CDM (left node) or in MRS (right node). Round nodes represent single genes with their corresponding lp_number, which is the number as annotated in the sequenced parental L. plantarum WCFS1 strain [16], green lines represent down-regulation, and red lines represent up-regulation of the gene compared to the parental strain. The colors of the round nodes represent the annotated main class.

**Figure S3** Lp_1669 regulon hybridization scheme. Tail and head of the arrow represent Cy3 and Cy5 labeling, respectively.
