Abstract

1. Ecotones, characterized by adjacent yet distinct biotic communities, provide natural laboratories in which to investigate how environmental selection influences the ecology and evolution of organisms. For wild herbivores, differential plant availability across sharp ecotones may be an important source of dietary-based selection.

2. We studied small herbivore diet composition across a sharp ecotone where two species of woodrat, Neotoma bryanti and N. lepida, come into secondary contact with one another and hybridize. We quantified woodrat dietary preference through trnL metabarcoding of field-collected fecal pellets and experimental choice trials. Despite gene flow, parental N. bryanti and N. lepida maintain distinct diets across this fine spatial scale, and across temporal scales that span both wet and dry conditions.

3. Neotoma bryanti maintained a more diverse diet, with Frangula californica (California coffeeberry) making up a large portion of its diet. Neotoma lepida maintains a less diverse diet, with Prunus fasciculata (desert almond) comprising more than half of its diet. Both F. californica and P. fasciculata are known to produce potentially toxic plant secondary compounds (PSCs), which should deter herbivory, yet these plants have relatively high nutritional value as measured by crude protein content.

4. Neotoma bryanti and N. lepida consumed F. californica and P. fasciculata, respectively, in greater abundance than these plants are available on the landscape—indicating dietary selection. Finally, experimental preference trials revealed that N. bryanti exhibited a preference for F. californica, while N. lepida exhibited a relatively stronger preference for P. fasciculata. We find that N. bryanti exhibit a generalist herbivore strategy relative to N. lepida, which exhibit a more specialized feeding strategy in this study system.

5. Our results suggest that woodrats respond to fine-scale environmental differences in plant availability that may require different metabolic strategies in order to balance nutrient acquisition while minimizing exposure to potentially toxic PSCs.
1 | INTRODUCTION

Ecotones are characterized by spatial transition in environmental variables that can create selective gradients that generate or maintain diversity (Smith et al., 1997). When sharp abiotic gradients support the establishment of spatially proximate but distinct vegetation communities (Walker et al., 2003), animals must respond to abrupt spatial transitions in abiotic and biotic resources. Such spatially proximate, yet dissimilar selective environments have the potential to generate or reveal the ecological adaptations or forms of phenotypic plasticity that permit species to exist in disparate environments (Ghalambor et al., 2007; West-Eberhard, 1989).

At sharp environmental transitions, one of the primary challenges facing herbivores is the abrupt transition in food plant availability. For herbivores, space use and movement across ecotones is largely determined by the distribution of plants that allow acquisition of adequate nutrition, while minimizing exposure to toxic plant secondary compounds (PSCs; Dearing et al., 2000, 2005; Freeland & Janzen, 1974; Westoby, 1978). Mammalian herbivores have evolved numerous behavioral and physiological adaptations to maximize nutrition while minimizing toxin exposure including regulation of liver detoxification enzymes (Malenke et al., 2012), decrease in metabolic rate and physiological activity when exposed to dietary PSCs (Sorensen et al., 2005b), and maintenance of a microbiome that facilitates nutrient acquisition and detoxification (Kohl et al., 2014). Mammalian herbivores may also diversify their diets to minimize overexposure to, or neutralize, toxins present (Iason & Villalba, 2006). Based on the degree to which mammalian herbivores modify their diets either spatially or temporally, they can be classified along a continuum of foraging strategies from generalist to specialist consumers (Shipley et al., 2009).

When mammals consume toxic plants they are not adapted to, they suffer energetic consequences that can lead to rapid weight loss and lowered body condition (Mangione et al., 2004; Sorensen et al., 2005a, 2005b). Given these consequences, we would expect mammalian herbivores to develop dietary preferences for plants with which they are familiar and which they can efficiently digest (Partridge, 1981). Hence, for herbivorous mammals, distinct vegetation communities across sharp ecotones may produce spatial variation in selection that leads to or reinforces distinct dietary preferences, which may in turn determine fine-scale space use and a range of intra and interspecific interactions (Nosil et al., 2005; Via, 1999; Via et al., 2000).

One such ecotone exists on the western edge of the Kelso Valley, California where the southeastern slopes of the Sierra Nevada meet the valleys of the western Mojave Desert. Two closely related species of woodrat meet at this sharp ecotone: Neotoma bryanti (Bryant’s woodrat) that primarily occur in the relatively mesic woodland and chaparral habitat of a rocky hill (hereafter called the “hill”), and N. lepida (Desert woodrat) that occur primarily in the adjacent Mojave Desert scrub habitat (hereafter called the “flats”; Shurtliff et al., 2014, Figure 2). The two species are estimated to have diverged ~1.6 mya based on mtDNA (Figure 1; Patton et al., 2007), and while they are largely spatially segregated between the two adjacent habitats, they do occasionally hybridize. These hybridization events lead to approximately 14% of individuals across the study site having hybrid ancestry, with backcrossing and introgression in both parental directions (Shurtliff et al., 2014; J. P. Jahner, T. L. Parchman, M. D. Matocq, unpublished data). Previous diet analyses (Matocq et al., 2020; Shurtliff et al., 2014) suggest that N. bryanti and N. lepida consume distinct diets in the hill and flats, respectively. As such, this system offers an opportunity to investigate dietary choices across a sharp ecotope, as well as the potential role of dietary differences in limiting interspecific contact and hybridization.

Here, we sought to further characterize the degree to which dietary composition and preference differ between pure N. bryanti and N. lepida in their respective native habitats, and to uncover the potential ecological correlates maintaining species differences in diet across this ecotone. We integrate both field and laboratory studies to ask the following questions: (1) Do N. bryanti and N. lepida maintain distinct diets across this sharp ecotone in both wet and dry seasons, and in wet and dry years? (2) Do these species consume plants in the wild in proportion to their availability in the habitat, or do they exhibit selection/preference for particular plants? (3) When given a choice in experimental trials, do woodrats exhibit the same dietary preferences as exhibited in field-collected samples? (4) To what degree are plant nutritional content and plant secondary compounds correlated with dietary preferences? To address these questions, we quantify diet preferences in the wild using high-throughput sequencing of the chloroplast trnL intron from woodrat fecal samples collected across the ecotone. We further examine these apparent patterns of preference by conducting an experimental choice trial. To understand the underlying drivers of fine-scale diet differentiation in this system, we place these dietary preferences within the context of availability of these plants on the landscape, the plant secondary compound composition of these plants, and their nutritional quality. Our study provides a well-developed example of fine-scale diet differentiation in mammalian herbivores—differences across an ecotone that are maintained between the species in both wet and dry conditions.

2 | MATERIALS AND METHODS

2.1 | Study system

The study site is located in Kelso Valley, Kern Co., California, where N. bryanti and N. lepida meet and hybridize at the southwestern end of the Sierra Nevada mountain range (35°25′45N,
The mesic “hill” habitat sharply transitions to the xeric “flats” habitat (Figure 1), and both parental species and hybrids can be found across a span of as little as tens of meters. The total area of the study site is approximately 50 hectares, approximately centered at the base of the hill (Figure 1). We conducted vegetation surveys in 27 plots (hill = 16, flats = 11) to estimate the abundance of the most common shrubs and trees (details in Supporting Information).

2.2 Woodrat species identity

We identified individuals as N. bryanti or N. lepida using microsatellite loci previously developed for these species (Sousa et al., 2007). For animals included in the preference trials (see below), we obtained ear biopsies from each individual and conducted DNA extraction, amplification and scoring of microsatellite loci as described in Coyner et al. (2015). We established species identity by conducting a Bayesian assignment test as implemented in STRUCTURE (Pritchard et al., 2000; Falush et al., 2003) at K = 2 as in Shurtliff et al. (2014) and used q_{lepida} values >90% to assign individuals to N. lepida and q_{lepida} values <10% to assign individuals to N. bryanti. To confirm the species identity of individuals included in the fecal metabarcoding, we used the same genotyping approach, but started with the gDNA extractions used for trnL sequencing (see below) and performed three replicate PCRs per sample.

2.3 Fecal metabarcoding

To determine the dietary composition of N. bryanti and N. lepida at our site, fecal samples were collected from 35 unique woodrat nests during March-August of 2016. Species identity for fecal pellets was confirmed with microsatellite markers as described above. Clusters of approximately 10–20 fresh pellets were collected from N. bryanti nests in the hill habitat (n = 19) and N. lepida nests in the flats habitat (n = 16). These samples provided insight into diet in the spring months of March - May (N. bryanti = 11, N. lepida = 11) and summer months of July and August (N. bryanti = 8, N. lepida = 5). To ensure fecal pellets were characteristic of the sampling period, we located active latrines at woodrat nests and swept away all fecal material; after 3–4 nights, we collected fresh, adult-sized fecal pellets. It is important to note that woodrat houses are solely occupied by one adult woodrat, and these animals are highly territorial, so there is limited chance that more than one woodrat contributed to the fresh fecal pellets we collected. We placed pellets into coin envelopes to
Dry, and stored them long-term at −20°C. We submitted samples to Jonah Ventures LLC for sequencing of a portion of the chloroplast trnL intron to reconstruct relative summer diet composition (methods including extraction, PCR amplification, sequencing, and raw data processing in Supporting information). We removed operational taxonomic units (OTUs) that did not occur in at least one sample with more than 1% abundance. We confirmed identity of remaining OTUs by conducting a BLASTn search (https://blast.ncbi.nlm.nih.gov). The potential presence of a plant at the study site was determined based on our own field collections and the CalFlora database (https://www.calflora.org/). If a resulting search returned more than one possible species, genus, or family that might occur at the site, we report the highest level of taxonomy (i.e., genus, family). Finally, to confirm the trnL primers used would detect the most common plants at the site, and to generate known sequences (i.e. vouchers) for these plants, we sequenced the following collected at the study site: Eriogonum nauseosum, Artemisia tridentata, Eriogonum fasciculatum, Prunus fasciculata, Frangula californica, and Phacelia tanacetifolia.

### 2.4 | Diet composition

We used read counts of all identified plants to calculate Shannon diversity for diets of N. bryanti and N. lepida and performed a two-sample t-test in R to compare diversity in diet composition (R Core Team, 2016). We used read counts to determine if diets between the two species were distinct by performing a PERMANOVA using Bray–Curtis distances with the adonis function in the vegan package (Oksanen et al., 2013; R Core Team, 2016).

To estimate individual and population-level (i.e., species) consumption of particular plants, we used both frequency of occurrence (FOO) and relative read abundance (RRA) of plant taxa identified in fecal samples. We considered a plant taxon present if it made up 1% or more of the total reads in a sample (Deagle et al., 2019). We calculated RRA for each plant within individual samples, and then averaged RRA values for N. bryanti and N. lepida. We used the signassoc function in the R package indicpecies (De Cáceres & Legendre, 2009) on the resulting presence/absence matrix and RRA datasets to determine which plants were significantly associated with either N. bryanti or N. lepida. Average RRA values have traditionally been viewed with caution as they are prone to recovery bias and other artifacts, but the information contained within read counts can still provide important insights into the relative importance of certain plants at the population level (Deagle et al., 2019). Previous authors have reported correlation between relative abundance of plants consumed and raw number of reads obtained ($r^2 = .75$, $p < 10^{-15}$; Willerslev et al., 2014), and while FOO is less affected by recovery bias, RRA can provide a more accurate characterization of population-level diet (Deagle et al., 2019). We sought to incorporate measures of presence/absence (FOO) and relative abundance (RRA) to characterize dietary differences at the population level in this study.

In order to take individual variation into account in estimates of population-level consumption, we used a hierarchical Bayesian approach implemented in R using the bayesr package (Fordyce et al., 2011) to estimate population-level consumption of the 5 most common plants identified in woodrat diets, which comprised 80%–90% of total reads (Tables 1 and S1–S3). We pooled the remaining read counts from all other plant taxa into an “other” group. Rather

### Table 1 Frequency of occurrence (FOO), relative read abundance (RRA), and where applicable, the percent abundance of woody plants in each habitat of plants identified in the diets of N. bryanti and N. lepida

| Taxa identified        | N. bryanti (n = 19) | N. lepida (n = 16) | p-Value |
|------------------------|---------------------|--------------------|---------|
|                        | FOO     | RRA    | %hill | FOO     | RRA    | %flats | FOO | RRA |
| Prunus fasciculata     | 0.21    | 0.04   | 0.04  | 1.00    | 0.79   | 0.10   | 0.01 | 0.01 |
| Frangula californica   | 0.89    | 0.41   | 0.13  | 0.06    | <0.01  | 0.01   | 0.01 | 0.01 |
| Phacelia tanacetifolia | 0.89    | 0.11   | 0.11  | 0.82    | 0.14   |        | 0.65 | 0.34 |
| Pinus spp.             | 0.84    | 0.19   | 0.05  | 0.12    | <0.01  | <0.01  | 0.01 | 0.01 |
| Eriogonum umbellatum   | 0.68    | 0.08   | 0.08  | 0.24    | 0.03   |        | 0.01 | 0.16 |
| Ribes amarum           | 0.32    | 0.04   | 0.03  | 0.00    | 0.00   | 0.00   | 0.06 | 0.01 |
| Acmispon americanus    | 0.32    | 0.03   | 0.03  | 0.00    | 0.00   | 0.00   | 0.08 | 0.03 |
| Asteraceae             | 0.37    | 0.02   | 0.02  | 0.12    | <0.01  | 0.14   | 0.14 | 0.17 |
| Eriogonum nauseosum_voucher | 0.21 | <0.01  | 0.33  | 0.00    | 0.00   | 0.60   | NA  | NA  |
| Euphorbia maculata     | 0.00    | 0.00   | 0.00  | 0.24    | 0.02   |        | 0.10 | 0.06 |
| Cercocarpus betuloides | 0.16    | 0.01   | <0.01 | 0.00    | 0.00   | 0.23   | 0.23 | 0.29 |
| Salvia columbariae     | 0.21    | <0.01  | 0.21  | 0.00    | 0.00   |        | 0.20 | 0.10 |

Note: Here we include only those plants that occurred with FOO > 15% in spring and summer 2016 combined (full dietary plant list in Tables S1–S3). p-Values are corrected for multiple comparisons. We confirmed the presence of E. nauseosum voucher sequences in some samples and therefore list FOO and RRA for those within the larger Asteraceae family. Bold indicates statistical significant p values. Lastly, we considered diet composition of N. bryanti and N. lepida in this study (2016, a wet year) relative to that found previously (2013, a dry year; Matocq et al., 2020). We compare RRA values as consumption of plant food was not modeled for 2013 data.
2.5 | Crude protein content of common shrubs

We characterized the nutritional value of common shrubs in each habitat and/or those that were most common in woodrat diets (see below) by measuring relative crude protein content. Crude protein content is considered the best single factor for determining nutritional value of forage plants (Samson & Jesperson, 1963, pg. 20). We collected leaves and fresh green growth of *F. californica*, *P. fasciculatum*, *E. nauseosa*, *A. tridentata*, and *E. fasciculatum* in summer and dried at ambient temperature. We estimated crude protein on the dry matter basis using the Kjeldahl method (Association of Official Analytical Chemists, 2002). In short, one gram of dried plant material was ground and digested in boric acid prior to titration to measure nitrogen content, which was multiplied by a factor of 6.25 (Association of Official Analytical Chemists, 2002).

3 | RESULTS

3.1 | Vegetation community

The most common shrubs and trees on the hill were *E. nauseosa* (33%), *E. fasciculatum* (16%), *F. californica* (13%), Ephedra sp. (11%), Hesperoyucca whipplei (7%) and multiple species of *Pinus* (5%). The most common shrubs and trees in the flats were *E. nauseosa* (60%), *E. fasciculatum* (11%), Yucca brevifolia (11%), *P. fasciculata* (10%), and *A. tridentata* (6%). Relative proportions of all subshrubs, shrubs and trees are provided in the Supporting materials (Figure S1, Table S4). Vegetation diversity was greater on the hill (*H = 1.50*) than the flats (*H = 0.93, t = -4.40, df = 16.93, p < .001*), and vegetation community composition differed between the hill and flats (*MS = 1.83, r² = .33, p = .001*). Of 91 woodrat nests in the flats, 59% were either directly at the base of *P. fasciculata* or were located in rocks with *P. fasciculata* adjacent, while the remaining were in *Y. brevifolia*, *E. nauseosa*, and *R. amarum*. Woodrat nests on the hill were primarily within large boulders with little if any immediately surrounding vegetation.
3.2 | Diet composition, relative frequency of occurrence and relative read abundance

After filtering and verifying OTU representative sequences, we retained 847,690 reads from 35 woodrat fecal samples that represented 33 plant taxa (Tables 1 and S1–S3). During spring, diet diversity was greater in N. bryanti (H = 1.32) than in N. lepida (H = 0.71; t = 4.30, df = 19.87, p < .001), and diet composition was also distinct between N. bryanti and N. lepida (MS = 2.81, r² = .46, p = .001). During summer, diet diversity was also greater in N. bryanti (H = 1.16) than in N. lepida (H = 0.41; t = 5.51, df = 9.69, p < .001), and diet composition was also distinct between N. bryanti and N. lepida (MS = 1.99, r² = .60, p = .003). When data from both seasons were combined, diet diversity in N. bryanti (H = 1.25), was twice that of N. lepida (H = 0.62; t = 5.77, 32.92, p < .001), and diet composition was also distinct between the species (MS = 4.82, r² = .50, p = .001). In addition to the plants recovered from fecal samples, we confirmed that our primer set was able to recover the five common shrubs on which we tested them. Of note is that our known sequences for Ericameria and Artemisia are not different from many other species in the Asteraceae, thus all these similar sequences are collapsed into the Asteraceae (Tables 1 and S1–S3).

Overall, N. bryanti and N. lepida exhibit distinctly different diets, but do consume some of the same plants. The frequency of occurrence (FOO) and relative abundance (RRA) of all 33 plant taxa identified may be found in Tables 1 and S1–S3. Notably, N. bryanti exhibited a more diverse diet with F. californica as the most abundant food item in spring and summer combined (FOO = 0.89, RRA = 0.41; Table 1). Pinus spp. and Phacelia tansyfola also occurred in the diet of N. bryanti with greater than 80% FOO and over 10% RRA in spring and summer combined (Table 1). Neotoma bryanti increased consumption of F. californica in summer relative to spring evidenced by increases in both FOO and RRA (Figure 2, Tables S1 and S2). Neotoma lepida consumed a less diverse diet, with P. fasciculata being the most abundant in spring and summer (FOO = 1.00, RRA = 0.79; Table 1). Neotoma lepida increased consumption of P. fasciculata from spring to summer (RRA_{spring} = 0.74, RRA_{summer} = 0.91; Figure 2, Tables 1 and S1 and S2). Overall, RRA for the Asteraceae family did not exceed 2% for either N. bryanti or N. lepida and the overall frequency of occurrence was also low (FOO_{bryanti} = 0.37, FOO_{lepida} = 0.12). Thus we are confident that, even with our inability to discriminate within the Asteraceae family, woodrats consume very little if any E. nauseosa or A. tridentata at our site.

Results of our hierarchical Bayesian modeling were consistent with diet composition based on FOO and RRA estimates. Notably, estimates of consumption using bayespref were less extreme than those from average RRA values (Tables 1 and S1–S3, S5, Figure 2). Frangula californica was still the most common single plant in the diet of Neotoma bryanti and increased from spring to summer (consumption_{spring} = 0.22 [95% CI 0.14–0.30], consumption_{summer} = 0.36 [95% CI 0.26–0.45]; Table S5, Figure 2). More than half the diet of N. lepida was composed of P. fasciculata also increased from spring to summer (consumption_{spring} = 0.54 [95% CI 0.45–0.61], consumption_{summer} = 0.65 [95% CI 0.56–0.71]; Table S5, Figure 2). While diets of N. bryanti and N. lepida were vastly different, Phacelia tanacetifolia, an annual forb, was found to make up ~13%–19% of the diet of both species (Table S5, Figure 2).

Our measures of diet composition in this study were largely consistent with those previously described in Matocq et al. (2020). Their measure of diet occurred during the summer of 2013, an extreme drought year, wherein Neotoma bryanti consumed a high level of F. californica (RRA = 0.52) and N. lepida consumed large amounts of P. fasciculata (RRA = 0.59; Matocq et al., 2020). During spring of a wet year (2016; this study), when more vegetation diversity was available, N. bryanti reduced consumption of the “difficult” F. californica relative to summer (RRA_{spring} = 0.35, RRA_{summer} = 0.51). In contrast, N. lepida maintained high levels of P. fasciculata in its diet whether an extreme drought year summer (see above) or a wet-year summer (i.e., 2016, RRA_{summer} = 0.91. Even during a “superbloom” spring, arguably the highest diversity this site experiences, N. lepida still consumed high quantities of P. fasciculata (RRA_{spring} = 0.74).

3.3 | Crude protein content

Prunus fasciculata and F. californica had among the highest levels of summer crude protein content, 15.1% and 12.4% respectively (Table 2). Our measurements of crude protein for E. nauseosa, A. tridentata, and E. fasciculatum were 8.0, 8.4, and 5.1, respectively. Sampson and Jesperson (1963) reported average crude protein content of F. californica leaves as high as 19% from April to August. Summer crude protein content of A. tridentata was reported at 9.9%
during August, with values as high as 15% during spring (Sampson & Jesperson, 1963; Welch, 1989). Crude protein content of *E. nauti-seosa* can range from a minimum of 9% to a high of 11.8% when new growth forms (Sampson & Jesperson, 1963). Crude protein content of *E. fasciculatum* varied from 5.4% in summer to 8.6% for new growth (Genin & Badan-Dangon, 1991). We were unable to find reported crude protein content of *P. fasciculata* in the literature.

### 3.4 Preference trials

A total of 27 individuals were included in diet trials: *N. bryanti* (*n* = 15), *N. lepida* (*n* = 12). We found that preference was significantly different between species (*p* < .001, Table 3). *N. bryanti* exhibited a preference for *F. californica* (preference = −0.47 [95% CI −0.66 to −0.28], while Neotoma *lepida* preferred *P. fasciculata* (preference = 0.61 [95% CI 0.41–0.81]; Figure 3). There was variation in preference index among individuals. However, all *N. lepida* individuals showed preference for *P. fasciculata* with two individuals consuming only that plant, and all *N. bryanti* individuals showed preference for *F. californica* with two individuals consuming only that plant.

| Variable         | Estimate | SD    | t Value | p-Value |
|------------------|----------|-------|---------|---------|
| (Intercept)      | −0.19333 | 0.17713 | −1.091  | .2880   |
| *N. lepida*      | 1.17135  | 0.14086 | 8.316   | <.001   |
| Sex              | −0.13788 | 0.13989 | −0.986  | .3361   |
| Mass change in   | −0.16515 | 0.08127 | −2.032  | .0556   |
| trial            |          |        |         |         |
| Year             | −0.50832 | 0.31591 | −1.609  | .1233   |
| Duration of      | −0.17816 | 0.16896 | −1.054  | .3042   |
| Trial            |          |        |         |         |
| Food Type        | 0.04444  | 0.20654 | 0.215   | .8318   |

Note: The dependent variable was the preference index for either *F. californica* or *P. fasciculata*—measured as the amount of *P. fasciculata* minus the amount of *F. californica* consumed divided by the total amount of food consumed during the trial. Bold indicates statistical significant p values.

Results of overall model: Residual standard error: 0.3225 on 20 degrees of freedom; multiple R-squared: .8023; adjusted R-squared: .743; F-statistic: 13.53 on 6 and 20 degrees of freedom; p-value: <.001.

4 | DISCUSSION

Despite ongoing hybridization between *N. bryanti* and *N. lepida* (Shurtliff et al., 2014), we found differences in dietary preference and dietary composition between these two species; differences that were maintained in both wet and dry years, and across seasons. The primary plants differentially preferred by each species are nutritious relative to other available plants, but also potentially toxic in unique ways, suggesting these species may have evolved or developed distinct metabolic strategies to reduce toxin exposure. Given the degree of dietary plasticity we observed across seasons in natural diets and in preference trials, we find that *N. bryanti* is more of a dietary generalist than *N. lepida*. Dietary differences between the species likely contribute to their spatial segregation across the ecotone, which ultimately determines their opportunities for interspecific interactions, including hybridization.

At this ecotone, the vegetation of the hill community is more diverse and largely distinct from that of the flats, and this diversity and differentiation is partly reflected in the diets of the woodrats that occupy these habitats (Figure 2 and Figure S1, Tables 1 and S1-S3). Overall, dietary diversity of *N. bryanti* on the hill was twice that of *N. lepida* individuals living in the flats. Despite the diversity of plants consumed by *N. bryanti*, *F. californica* appears to predominate their diet. In contrast, *N. lepida* in the flats have a diet dominated by *P. fasciculata*. For both *N. bryanti* and *N. lepida*, these food plants (i.e., *F. californica* and *P. fasciculata*) were consumed at higher rates than their availability on the landscape, suggesting dietary selection (Hodgson, 1979).

During spring and summer of 2016, we show that the diet of *N. bryanti* on the hill is dominated by *F. californica* while the diet of *N. lepida* on the flats is dominated by *P. fasciculata*. However, we did find that some *N. bryanti* on the hill consumed a small amount of *P. fasciculata*, while *N. lepida* on the flats infrequently consumed *F. californica*. This result from our sample of wild diets is at least partly due to the relative rarity of these two plants in the “alternate” habitat. However, results of our 2-choice trial show that even when given a choice of both plants, on average, *N. bryanti* primarily consumed *F. californica* and *N. lepida* primarily consumed *P. fasciculata*. As such, on average, individuals in our experimental trial showed a preference for the plant they most commonly consume in the natural environment. Overall, our field and experimental results demonstrate that *N. bryanti* show a preference for *F. californica* and *N. lepida* show a preference for *P. fasciculata*, which may reflect differences in behavioral acclimation to different resources and/or underlying species differences in their ability to metabolize these particular plants.

Despite the overall preference *N. bryanti* and *N. lepida* exhibit for these plants, there was a great deal of individual variation in our experimental trials. Specifically, most individuals consumed at least some of the presumably novel plant. This is a foraging behavior animals may employ to identify new food resources (Partridge, 1981), and one we might expect when individuals are exposed to novel food items. This short-term consumption of a potentially novel, chemically distinct plant did not appear to have negative consequences for experimental animals as none lost excessive weight over this short period (i.e. >10% body mass) and animals remained alert and responsive. Overall, *N. bryanti* showed less extreme preference than *N. lepida* and these results are consistent with several *N. bryanti* on the hill consuming *P. fasciculata*, albeit in very low amounts, while *N. lepida* on the flats rarely consume *F. californica*. Both of these lines of evidence suggest that *N. bryanti* may be further towards the generalist end of the spectrum of specialization, while *N. lepida* may be further towards the specialist end of the spectrum (Shipley et al., 2009).
Herbivores may employ a range of dietary strategies, from specialist to generalist, to balance nutrient acquisition and exposure to plant PSCs. Specifically, facultative specialists exhibit diets largely restricted to a single "difficult" (i.e., potentially toxic) food item, but are capable of expanding their diet when resource availability allows. In contrast, facultative generalists typically maintain more diverse diets, but are capable of restricting their diets to a "difficult" plant when environmental conditions limit food resources. Given the potential toxicity of

\[ \text{Prunus fasciculata} \] (Matocq et al., 2020). At one extreme is the 2013 snapshot of diet composition, which was taken in summer of an extreme drought wherein California received less precipitation than in any previous year in the 119-year observational record (Swain et al., 2014), and few annual forbs were observed at the site (M. D. Matocq, personal observation). This is in contrast to conditions at the site during 2016 - a wet and warm year facilitated by El Niño conditions that led to a spectacular 2016 spring "superbloom" event (Treonis et al., 2019) characterized by high annual forb diversity across the Mojave desert. These snapshots of diet composition (i.e., 2013 and 2016) capture aridity extremes from centennial-scale drought, to wet-year summer, to wet-year spring, and thus, a plant diversity/availability gradient from low to high for this site. As expected, if \[ N. bryanti \] is a facultative generalist, high plant diversity in spring 2016 led to a decrease in consumption of \[ Frangula \] whereas, \[ N. lepida \] maintained high consumption of \[ Prunus \], regardless of availability of spring forbs. Others have classified \[ N. lepida \] as a facultative specialist (Dial, 1988; Shipley et al., 2009; Skopec et al., 2015), and our data support this classification. Indeed, \[ N. lepida \] can consume large quantities of what is considered to be a potentially toxic plant. Although \[ N. lepida \] is capable of consuming other plants at this site, individuals appear to prefer \[ P. fasciculata \] even when other options are available, suggesting local specialization on this plant. \[ Neotoma bryanti \] is also capable of consuming large quantities of a potentially toxic plant, \[ F. californica \]. Yet, when given the option, we observed that \[ N. bryanti \] will diversify its diet while still maintaining a high proportion of the "difficult" plant in its diet—further supporting \[ N. bryanti \] at this site as a facultative generalist. It should be noted that any study of diets in wild rodents that cache or hoard, as woodrats do, cannot discriminate between items that were eaten fresh versus those eaten after storage. Caching may reduce toxin content in plants, especially those with volatile compounds (i.e., \[ Juniperus \], Torregrossa & Dearing, 2009). While the primary compounds in \[ Frangula \] and \[ Prunus \] are not volatile, we do not know how these compounds would degrade over time if stored. Likewise, we do not know the extent to which woodrats at this site cache these plants.

Another critical ecological driver of diet composition and breadth at this study site is simply the presence of a closely related congener.
CONFLICT OF INTEREST

ACKNOWLEDGMENTS

We thank Michael Jee, Jason Wurtz, Dan Moore, and Angela Mitchell for assistance in field work. We thank Mozart Fonseca for use of his lab and equipment and Teshome Shenkori for assistance in measuring plant crude protein content. We thank the members of the UNR Evoldoers lab group for comments on earlier drafts of this manuscript. We thank Mary V. Price and one anonymous reviewer for helpful comments on this manuscript. We also thank M. Forister, J. Forbey, and D. Dearing for helpful discussions. This research was supported in part by the National Science Foundation (IOS-1457209 and OIA-1826801).

Specifically, the narrower dietary niche of N. lepida at this site could in part be driven by competition with N. bryanti. Shurtliff et al., (2013) showed in laboratory trials that the relatively large-bodied N. bryanti is more aggressive than the relatively small-bodied N. lepida. Interspecific competition is thought to be an important driver of dietary differentiation and fine-scale space use in interspecific contact zones between woodrats, with the large-bodied species typically monopolizing optimal nest sites (Cameron, 1971; Dial, 1988). Neotoma bryanti at this site monopolize what is likely the more optimal, relatively thermally stable boulder nesting area of the hill (Brown, 1968). We suspect inherent differences in behavioral, physical, and metabolic capabilities have allowed N. bryanti to monopolize the hill habitat with its diversity of dietary plants, while N. lepida have persisted at the site in part because of its ability to locally specialize on P. fasciculata.

Woodrats are well-known for their capacity to consume large quantities of potentially toxic plants (Larrea tridentata—Mangione et al., 2000; Juniperus sp.—Dial, 1988, Skopec et al., 2007). In particular, N. lepida is known to locally specialize on chemically distinct plants across its range (Larrea tridentata—Mangione et al., 2000; Juniperus—Stones and Hayward (1968), and here, P. fasciculata). The mechanisms that underlie a woodrat’s capacity to detoxify these diets likely include expression of their own detoxifying enzymes (Kitanovic et al., 2018; Malenke et al., 2012) and the activity of their gut microbiota (Kohl et al., 2014). Studies are needed to identify loci that are responsible for detoxification of different compounds, the degree to which specific alleles or pathways effectively metabolize particular PSC’s, and the interaction between mammalian and microbial genomes in creating toxin resistant phenotypes (Forbey et al., 2018). If unique metabolic adaptations or microbial combinations allow N. bryanti and N. lepida to metabolize different plants in their respective habitats, then migrant and hybrid individuals that do not possess habitat-specific genomic or microbial combinations may suffer reduced fitness (Nosil et al., 2005; Via, 1999; Via et al., 2000). Selection against migrants would minimize opportunities for interspecific contact and mating (prezygotic isolation), while selection against hybrids with suboptimal allelic or microbial combinations would further limit introgression between the species (postzygotic isolation). Continued integration of field and laboratory studies will be needed to identify the mechanisms that underlie metabolic processing of these diets, and how diet-related selection is influencing the evolutionary trajectory of these species.
