Abstract—We address the mobility management of autonomous UAV-mounted base station (UAV-BS) that provides communication services to a cluster of users on the ground while adhering to the problem constraints without affecting the delivered reward function. As our approach does not rely on any particular information about the users as well as the radio environment, it is flexible and respects the privacy concerns. Our experiments indicate that despite the minimum available information the UAV-BS is able to distinguish between high-rise (often non-line-of-sight dominant) and sub-urban (mainly line-of-sight dominant) environments such that in the former (resp. latter) it tends to reduce (resp. increase) its height and stays close (resp. far) to the cluster. We further observe that the choice of the reward function affects the speed and the ability of the agent to adhere to the problem constraints without affecting the delivered data rate.

I. INTRODUCTION

Using unmanned aerial vehicles (UAVs), also known as drones, benefits many applications including package delivery, search and rescue, infrastructure monitoring, law enforcement, and the like. Due to growing popularity and low cost, UAVs are getting an increased attention in the telecommunications sector to address on-demand data delivery, flexible backhauling, data harvesting, IoT applications, and caching. For example, due to their maneuverability, UAVs are exploited to enhance the performance of wireless communications via optimally deploying them as aerial (flying) base stations (UAV-BSs). This technique is shown to be particularly effective for those scenarios involving high (temporarily-lived) localized traffic surges, e.g. caused by crowded events, as well as network failure.

Our focus in this paper is to maximize the transmission capacity of UAV-BS to serve a cluster of users on the ground. This is a challenging problem given that the 3-D location of UAV-BS and geographical location of users on the ground affect signal propagation, and thus the transmission data rate, in a compound manner. Conventionally, to solve this optimization problem it is assumed that 1) users are located in a cluster that has particular mathematical features (for example a circular disk), which its boundaries are known, 2) accurate knowledge of the channel is available, and 3) the geographical locations of users are known, see, e.g., [5], [6], and [1]. In fact, often the optimal placement of UAV-BS assumes that the channel can be predicted using a (relatively) straightforward model that, in the core, exploits the users’ locations along with the knowledge of the radio environment (sub-urban vs. urban areas). Such a knowledge is used to fine-tune the path-loss and the shadowing parameters, and consequently to convert the original problem into an equivalent optimization problem which its objective function as well as constraints are functions of the location of UAV-BS. In reality, the information regarding the users’ locations may not be available due to privacy issues or simply the lack of such knowledge. Given that the solutions that are not intrusive regarding to the private information of the users is practically valuable, we, therefore, promote solutions based on deep reinforcement learning (DRL) to learn the navigation of UAV-BS in order to optimize the capacity.

In [8], deep Q-learning network (DQN) is used to design the trajectory of an autonomous UAV-BS without any explicit information about the environment. In order to increase the service time the use of landing spots is also promoted. Assuming a fixed altitude of the UAV-BS during the navigation, the action space of the UAV-BS is reduced to 8 movement directions. To minimize the mission completion time subject to maintaining good connectivity with the cellular network a temporal difference based DRL solution is suggested in [9]. The algorithm relies only on the raw signal strength as input. It is assumed that the UAV flies with fixed speed, therefore the agent needs only to adjust the direction of the UAV. Note that in all of these works its also assumed that the destinations are known to UAV prior to the start of the mission, which may not be the case for many scenarios.

To address the lack of geographical information of users, work of [10] discusses the use of UAV for search and rescue applications. Authors use UAV for locating a user merely by receiving the received signal strength (RSS) in an indoor environment using DQN. It is shown that DQN solution is competitive with the location-based solution, emphasizing the power of model-free DRL. In [11], DQN is used to provide connectivity via proper UAV placement in an urban environment when the location of the end user is unknown. The algorithm uses the signal-to-interference-and-noise ratio measurements and exploits 3D map of the topology in order to maintain good connectivity with the cellular network.

This work was supported by Huawei Canada Co., Ltd.
to account for the scatterers and blockages. In both papers, the action dimension of the UAV is limited to 4—up, down, left, right—and the speed is kept fixed. In reality, the mobility of the UAV-BS is in a continuous 3-D space, which requires a more sophisticated solutions. Also extracting information from a 3-D map via reconstruction of the environment can be costly (although very effective). We hence use only RSS values to navigate the UAV-BS.

In particular, we adopt trust region policy optimization (TRPO) algorithm which is a policy gradient DRL to learn the navigation in continuous 3-D space. Our experiments indicate that UAV-BS differentiates high-rise (often non-line-of-sight dominant) from sub-urban (mainly line-of-sight dominant) environments. In effect, while in the former it tends to reduce its height and stays closer to the cluster, in the latter it attempts to increase its height and keeps distance to the cluster. We also demonstrate that the choice of the reward function can affect the speed and the ability of the agent to adhere to the problem constraints without affecting the delivered data rate. Last, as our approach does not rely on any particular information about the speed and the ability of the agent to adhere to the problem constraints without affecting the delivered data rate. Last, as our approach does not rely on any particular information about the environment type (sub-urban versus high-rise), and the antenna beam-width of the UAV-BS, the agent needs to learn how to navigate in order to improve the quality of received signals as well as the transmission data rate. In general, it is too complex to accurately model such a relationship due to complex nature of the environment and mobility of the UAV-BS. As a remedy, we adopt model-free DRL solutions to tackle the involved complexity of the problem and to effectively deal with the lack of model.

II. PROBLEM FORMULATION

Our main focus is on 3-D navigation of the UAV-BS for providing communication services to a number of users that are geographically clustered (a.k.a. the area of interest). The UAV-BS receives RSS information from the users and accordingly adjusts its location via modifying its speed \( v \in \mathbb{R}^3 \) where \( |v| = v \in [v_{\text{min}}, v_{\text{max}}] \) m/s. The final goal is to improve the transmitted data rate. The UAV-BS should stay in the search area, which is assumed to be a large area with radius \( D_{\text{search}} \), during the service time. The maximum and minimum allowable height values (in meters) that the agent must respect is \( H_{\text{max}} \) and \( H_{\text{min}} \), respectively, which are imposed by the regulator. We consider a time-slotted model in which at the start of each time slot \( t \) the agent chooses a new speed \( v \) and keeps moving by that speed in the chosen direction unless otherwise it violates the boundaries. The speed is selected based on the received RSS information. We assume that the agent equally divides the time slots into \( K \) (the number of users) equal parts and schedules each user in each of them with the transmission power \( P/K \), where \( P \) is its instantaneous transmission power budget (per time slot). We also assume that the uplink channel (between users and UAV-BS that is dedicated to RSS) and downlink channel (between UAV-BS and users for data transmission) are frequently multiplexed. However, further information can be extracted from RSS information for provisioning a better scheduling and power allocation schemes, which is left for the future investigation.

The UAV-BS’ antenna is directional with beam-width \( \theta \), the main-lobe antenna gain \( G \), and side-lobe antenna gain \( g \) where \( G \gg g \).

Because the signal strength is a function of environmental factors such as distance between the agent and the users, radio environment type (sub-urban versus high-rise), and the antenna

beam-width of the UAV-BS, the agent needs to learn how to navigate in order to improve the quality of received signals as well as the transmission data rate. In general, it is too complex to accurately model such a relationship due to complex nature of the environment and mobility of the UAV-BS. As a remedy, we adopt model-free DRL solutions to tackle the involved complexity of the problem and to effectively deal with the lack of model.

III. POLICY GRADIENT DRL

The action of the UAV-BS is its speed in 3-D space, which belongs to continuous control. Here, we firstly provide a brief introduction to DRL. We then elaborate on TRPO to handle the navigation of the UAV-BS.

A. A Brief Introduction to Continuous DRL

In continuous DRL the agent (UAV-BS), operating in an uncertain environment with the continuous state and action spaces, interacts with the environment in a sequential style to learn an optimal policy (3-D speed) \([12]\). In each interaction the agent takes an action \( a_t \in \mathbb{R}^B \) (B is the action dimension) based on its observation of the environment state \( s_t \in \mathbb{R}^S \) (\( S \) is the dimension of the state space), which leads the agent to the new state \( s_{t+1} \) upon on collecting the bounded reward \( r_t \in \mathbb{R} \). The policy guides the agent to what action should be taken in a certain state in order to maximize the reward via maximizing the aggregate (discounted) expected reward \([7]\):

\[
J(\pi) = \mathbb{E}_\pi \sum_t \gamma^t r_t(s_t, a_t)
\]

by finding an optimal policy \( \pi_\theta(a_t|s_t) \) (or for short \( \pi_\theta \)) where \( \theta \) are the parameters of the associated DNN \( \pi(\cdot|\cdot) \). Parameter \( \gamma \in (0, 1] \) is the discount factor prioritizing short-term rewards and the expectation is on the policy \( \pi \) as well as the stochastic environment dynamics. In this paper, we focus on stochastic policies by which the DNN deterministically maps the state to a vector that specifies a distribution over the action space (i.e., \( a_t \sim \pi_\theta \)). To learn the policy we adopt policy gradient methods in which the gradient descent with respect to the average return \([1]\) is adopted \([7]\):

\[
\nabla_\theta J(\theta) = g = \mathbb{E}_{\pi_\theta} \sum_t \nabla_\theta \log \pi_\theta(a_t|s_t) A_\theta(s_t, a_t).
\]

Here we use the case that the policy gradient is formulated through the advantage function \( A_\theta(s_t, a_t) \), which is the subtraction of the Q-function and state-value function: \( A_\pi(s_t, a_t) = Q_\pi(s_t, a_t) - V_\pi(s_t) \). In practice, \( \hat{a} \) should be estimated over a batch of data collected from the current policy via Monte Carlo technique (sample based estimate of the policy gradient). The agent iteratively collects data

\[1\] For given policy \( \pi \), the state-value function \( V_\pi(s_t) \) measures the expected discounted reward from state \( s_t \) via \( V_\pi(s_t) = \mathbb{E}_{a_t, s_{t+1}, \ldots} \sum_{t' \geq t} \gamma^{t'-t} r_{t'}(s_{t'}, a_{t'}) \). The Q-function is similarly defined as \( Q_\pi(s_t, a_t) = \mathbb{E}_{s_{t+1}, a_{t+1}, \ldots} \sum_{t' \geq t} \gamma^{t'-t} r_{t'}(s_{t'}, a_{t'}) \), which is the state-value function for a given action.

\[2\] In the rest of this paper, we use symbol \( \hat{ \cdot } \) as the MC estimation of quantity \( x \).
In this form the optimization problem \( \hat{O} \) is not computationally affordable. An approximate version of the original optimization problem is then used:

\[
\hat{O} : \text{Maximize}_\theta \quad g^T(\theta - \theta_k) \quad \text{s.t.} \quad (\theta - \theta_k)^T F_{\theta_k}(\theta - \theta_k) \leq \delta_{KL}.
\]

where the objective function is the first-order approximation of the surrogate objective function and the constraint is the second-order approximation of the KL divergence constraint \([4]\). Here \( g \) is the policy gradient and \( F_{\theta_k} \) is the Fisher information matrix (FIM) associated to the average KL divergence at the current policy \( \theta_k \) \([14]\).

### Algorithm 1 TRPO

1: Hyper-parameters: KL divergence limit \( \delta_{KL} \), backtracking coefficient \( \alpha \), maximum number of backtracking steps \( n_B \), behavioral memory size \( M \), GAE lambda \( \lambda \in (0, 1) \), number of transitions \( N \)
2: Input: initialize policy parameters \( \theta_0 \), initial value function parameters \( \omega_0 \)
3: for \( k = 0, 1, 2, \ldots L \) do
   4: Collect \( N \) transitions \((s_t, a_t, r_t, s_{t+1})\) by running policy \( \pi \)
   5: Set \( \hat{R} = 0 \) and \( \hat{A} = 0 \)
   6: for \( t = N - 1, \ldots, 1 \) do
      7: Update the value network via gradient descent
      8: Estimate the policy gradient
      9: Use the conjugate gradient algorithm to compute \( \hat{x}_k = F_{\theta_k}^{-1} \hat{g} \)
   10: Update the policy parameters:
      \[
      \theta_{k+1} = \theta_k + \alpha \frac{2\delta_{KL}}{\hat{x}^T F_{\theta_k}^{-1} \hat{x}} \hat{x}_k, \quad j = \{0, 1, 2, \ldots, K\}
      \]
   11: Update the value network (via gradient descent)
      \[
      \omega_{k+1} = \arg\min_{\omega} \frac{1}{N} \sum_{t=0}^{N-1} \left( V_{\omega}(s_t) - \hat{R}[t] \right)^2.
      \]
   12: end for

### Updates Policy

Updating policy is based on solving optimization problem \( \hat{O} \) which is done in several steps (Step 5 to Step 10). First, we need to estimate the rewards-to-go \( \hat{R} \) and advantages \( \hat{A} \). In (7), \( d_t \in \{0, 1\} \), where \( d_t = 1 \) implies that the episode is terminated. As a result, the reward of the terminated time step of the episode is not included in
calculation of the advantages and rewards-to-go. On the other hand, in the calculation of the advantages \( \hat{A} \) we adopt the generalized advantage estimation (GAE) \([13]\) to improve the stability, where \( \lambda \in (0, 1) \) is a given parameter.

The estimated advantages are then used to estimate the gradient over the batch in Step 8. Steps 9 and 10 are to take the maximum step for updating the current policy. First, in Step 9 we derive a new direction via the conjugate gradient algorithm. Using conjugate gradient algorithm one is able to solve \( \tilde{F}_{k} \hat{x}_{k} = \tilde{g} \) through several iterations instead of resorting to the computation of the inverse of FIM, hence substantially increasing the computation efficiency and memory usage as the underlying DNN could have millions of parameters. Step 10 known as line search is a crucial step in TRPO algorithm as it ensures that the new policy, which is derived based on the approximation of the objective and the constraint, guarantees that actual surrogate objective (not its linear approximation) is improved while the KL divergence constraint (not its quadratic approximation) stays satisfied. In effect, the line search attempts to take possibly the largest legitimate step toward the next policy. For a given backtracking coefficient \( \alpha < 1 \) the parameters \( \theta_{l} \) are updated up to maximum backtracking steps \( J \). We terminate the line search when the smallest value \( \alpha^{j} \) (the bigger is \( j \), the smaller will be the update step) satisfies the KL divergence constraint and results in a positive surrogate value.

Value Network: The update of the value network \( V_{\omega_{k}} \) is done in Step 11. Using the rewards-to-go \( \mathbf{R} \) the value network is updated by mean-squared-error regression.

IV. EXPERIMENTS

For the experiments we use the pytorch library \([15]\). For each experiment we consider 6 different random seeds and calculate the average results accordingly.

A. Radio Environment

Now we discuss the communication model of the environment that are used to produce RSS values and transmitted data rates. We should emphasize that the provided information is only used for numerical evaluations and are not known to the agent. The UAV-BS is equipped with a directional antenna with beam-width of \( \pi/3 \). The main-lobe and side-lobe antenna gains for UAV are \( G = 2.6/\omega^{2} \) and \( g = G/100 \). The locations of each user \( k = 1, 2, \ldots, K \) is denoted by \( (X_{k}, Y_{k}) \in \mathbb{R}^{2} \bigcap B_{C} \), where \( B_{C} \) stands for the cluster’s geographical boundaries. The vertical angle between the receiver \( k \) and the UAV-BS is \( \rho_{k} = \tan^{-1}(H/||X_{k}||) \). The receiver \( k \) is within the main-lobe of the antenna, if \( \rho_{k} > \pi/2 - \omega/2 \), or equivalently for \( ||X_{k}|| < H/(\tan(\pi/2 - \omega/2)) \) \([16]\). The probability that the channel between UAV-BS and the receiver is in LOS status is obtained from \( p_{L}(||X_{k}||) = \left( 1 + \phi e^{\nu \left( \frac{180}{\pi} \arctan\left( \frac{H}{||X_{k}||} \right) - \phi \right)} \right)^{-1} \), where \( \phi \) and \( \nu \) are the channel parameters representing the characteristics of the communication environment (see Table I). Note that the 3-D distance between UAV-BS and user \( k \) is \( \sqrt{H^2 + ||X_{k}||^2} \). The log-normal gain is also modelled via \( \chi_{k} = 10^{\nu_{k}/10} \)

\[
U_{k} \sim N(\mu_{l}, \sigma_{l}^2) \quad \text{in which} \quad \sigma_{l}^2 = \sigma_{l} e^{-c_{l} \frac{\chi_{l}}{180} \arctan\left( \frac{H}{||X_{k}||} \right)} \]

To achieve the update step) satisfies the KL divergence constraint and results in a positive surrogate value.

\begin{align*}
\phi & = 27.23 \quad 12.08 \quad 9.61 \quad 4.88 \\
\nu & = 0.08 \quad 0.11 \quad 0.16 \quad 0.43 \\
\sigma & = 1.5 \quad 1 \quad 0.6 \quad 0 \\
\mu & = 29 \quad 20 \quad 17 \quad 18 \\
\sigma_{l} & = 7.37 \quad 8.96 \quad 10.39 \quad 11.25 \\
\sigma_{l} & = 37.08 \quad 35.97 \quad 29.6 \quad 32.17 \\
\sigma_{N} & = 0.03 \quad 0.04 \quad 0.05 \quad 0.06 \\
\sigma_{N} & = 0.03 \quad 0.04 \quad 0.03 \quad 0.03
\end{align*}

TABLE I

AIR-TO-GROUND PARAMETERS AND THE CORRESPONDING VALUES \([4]\).

In the experiments, we consider two radio environments: \( env = 0 \) (high-rise) and \( env = 3 \) (sub-urban). We consider a circular search area with radius 2000 meters and locate the cluster at position \( (1500, 1500) \) \( \in \mathbb{R}^{2} \). We assume the cluster is circular with radius 100 meters. We then randomly locate 10 users in the cluster. We also set \( H_{\text{min}} = 40 \) m. \( H_{\text{max}} = 150 \) m, \( v_{\text{min}} = 0 \) m/s, and \( v_{\text{max}} = 100 \) m/s. Note that users may dislocate in the cluster, but they always stay in the cluster. We compared the delivered rate with a heuristic approach in which the agent knows the location of the cluster and the locations of the users. The agent simply locates itself in the middle of the cluster and chooses its height such that all the users stay in the main-lobe of its antenna. We then study the data rate ratio \( \Delta_{d} \) that is the transmitted data rate over the data rate achieved under the heuristic approach.

B. Policy and Value Networks

Policy is modelled stochastically as a multivariate Normal distribution with diagonal covariance matrix. The mean of this distribution is a DNN with 3 dens layers. The first and second layers are with input/output dimensions \( S/400 \) and \( 400/300 \) respectively, where \( S \) is the space dimension. This DNN has two heads, one for the mean value and the other for the logarithm of the standard deviation. Each of these are modelled by its associated dense layer with size \( 300/B \) where \( B \) is the action dimension (number of users). Similarly, the value net is also a DNN with three layers with the difference that the last layer has dimensions \( 300/1 \). The activation functions are Tanh \([17]\). The state space is the stacked received RSS values from all users. Regarding TRPO algorithm, we set \( \delta_{KL} = 0.02 \), \( \lambda = 0.94 \), \( N = 10000 \), \( L = 4000 \), \( \gamma = 0.99 \), and \( T = 500 \).
C. Impact of Reward Function

Choosing a right form of the reward in navigation of UAV-BS is complex given that the action, which carries out the navigation, should be done based on RSS values while the actual goal is the maximization of the transmission data rate. In this case, it is not trivial to figure out how to optimally combine these components. Yet, we could compose the reward in the way that it promotes the agent to take constructive actions while adheres to physical limitations via imposing suitable penalties. For our experiments we consider two reward functions:

\[ r_2 = \sum_k (R_k + 0.01 \frac{r_{rss}}{\sigma}) - 5\Delta_a \]

\[ r_1 = \frac{0.1(\sum_k R_k + 0.01 \sum_k \frac{r_{rss}}{\sigma})}{\sum_k (R_k + 0.01 \frac{r_{rss}}{\sigma})} - 5\Delta_a \]

where \( R_k \) is the transmitted data rate to user \( k \). In both formulations the form of the reward function promotes the movement toward receiving larger values for RSS as well as delivering higher transmission data rate. As the signal attenuations are highly affected by the path-loss attenuation, which is a function of distance, we expect higher RSS values correlate with higher transmission data rate (but this is not guaranteed to take place due to the effect of shadowing and fading in the frequency multiplexed systems). Here, \( \Delta_a \) is the sum of the penalties associated with the feasible action (to enforce the constraints associated with the magnitude of speed \( [v_{min}, v_{max}] \), and azimuth angle \( [0, 2\pi] \), and polar angle \( [0, \pi] \) and the search region boundaries (to enforce the constraints regarding the altitude \( [H_{min}, H_{max}] \)

and search area \((-2000 \leq x \leq 2000, -2000 \leq y \leq 2000\)). As seen, compared to \( r_2 \), in \( r_1 \) the actual reward is scaled depending on whether the agent receives penalty or not. This could discourage the agent from unacceptable actions. However, via small rewards assigned to the violating actions the agent is reminded that the actions were still constructive. In the formulation of \( r_2 \) such a distinction is not provisioned, hence the agent may encounter difficulties to distinguish beneficial actions out of heavy penalties.

We now investigate which form of reward benefits the agent better in learning the task. For this experiment, we consider high-rise environment \((env = 0)\). From Fig. 1a we observe that the agent gains higher rewards under \( r_2 \) initially compared to \( r_1 \). However, both of the rewards achieves almost the same average reward. On the other hand, from Fig. 1b we note that the agent is able to learn the action boundaries very fast under both reward forms. However, as we see from Fig. 1c, under the reward function \( r_1 \) the agent is able to more strictly adhere to boundary limits of the search region compared to \( r_2 \). Finally, Fig. 1d shows that under both forms of reward the agent is able to gather almost the same values of RSS.

From Fig. 2a we see that the choice of reward substantially affects the average speed of the agent. In effect, under \( r_1 \) the agent tends to take higher speed values compared to \( r_2 \). This might be due to the fact that the agent attempts to correct its boundary violating actions (see Fig. 2c). This is also shown itself in the the height of the agent under \( r_1 \). Fig. 2c shows the distance of the agent to the center of the cluster \( \Delta_x \). We observe that under both reward functions the agent learns
to get closer to the cluster center as a way to improve the transmission data rate. We should note that the agent learns this behavior merely based on RSS signals, which is interesting. Finally, in Fig. 2d we show the data rate ratio $\Delta_r$ under both reward functions. We observe that under both rewards the agent is able to improve its data rate. Interestingly, the agent is able to achieve 40% of the heuristic scenario only based on RSS values. We also note that both rewards are (almost) equally effective.

Consequently, while the choice of the reward does not have any substantial impact on the transmitted data rate, distance to the cluster, and action penalty, it has a profound impact on the speed profile, the altitude of the agent, and how effectively the agent is able to adhere to the search region boundaries. We therefore consider $r_1$ in the rest of our experiments.

D. Impact of Radio Environment

Here, we attempt to demonstrate whether the agent is able to recognize the impact of radio environment from the RSS values and how she is responding to such a recognition. We consider two radio environments $\text{env} = 0$ (high-rise) and $\text{env} = 3$ (sub-urban). Results are shown in Fig. 1 and Fig. 2. As seen from Fig. 1a, Fig. 1d, and 2d, for an agent in $\text{env} = 3$ the reward, average RSS values, and the transmission data rate is much higher than compared to the case of $\text{env} = 0$. This is because in the former the environment is more LOS dominant compared to the latter, hence the signals go under less severe attenuations. The question is then how the agent incorporates such recognition in its mobility?

From Fig. 2a we observe that for the agent in $\text{env} = 3$ the magnitude of the speed is higher compared to the one performing in $\text{env} = 0$. Interestingly, the higher speed is used for gaining much higher height (see 2b). As a result, the agent recognizes that for the radio environment with dominant LOS component there is no need to get too close to the center of the cluster if the height is properly adjusted. As seen, this strategy can result in a decent rate transmission (about 60% of the rate in the heuristic scenario is achieved). On the other hand, for $\text{env} = 0$ the agent attempts to get closer to the cluster’s center (see 2c) and simultaneously reduces its height (2b) as an effective approach to circumvent relatively higher path-loss.

V. CONCLUSIONS

We addressed the mobility management of UAV-BS in a 3-D space to support a cluster of users on the ground while the geographical characteristics (e.g., location and boundary) of the cluster as well as the geographical location of the users are not available. The agent aimed at maximizing the data rate while the characteristics of the radio environment are not known and may be extracted merely from the received signal strength (RSS) from the users. We adopted deep reinforcement learning to deal with the lack of model. In particular, we adopted TRPO algorithm, which is an on-policy policy gradient DRL, to adjust the (continuous) speed of UAV-BS only based on RSS values. Our experiments suggested that the choice of the reward substantially affects the speed profile and the ability of the agent to adhere to its physical constraints. Interestingly, we observed that UAV-BS was able to distinguish between high-rise (less LoS dominant) and sub-urban (mainly LoS dominant) environments.
