ABSTRACT

Outbreaks of carbapenemase-producing *Klebsiella pneumoniae* (CPKp) represent a major threat for hospitals. We molecularly characterized the first outbreak of VIM-1-producing *K. pneumoniae* in Spain, which raised fears about the spread of this strain or of the plasmid carrying *bla*VIM-1. Through in-depth genomic analysis of 18 isolates recovered between October 2005 and September 2007, we show that 17 ST39 isolates were clonal, whereas the last isolate had acquired the VIM-1 plasmid from the epidemic clone. The index isolate carried 31 antibiotic resistance genes (ARGs) and was resistant to almost all antibiotics tested. Later isolates further gained mutations in efflux pump regulators *ramR* and *opxR*, deletion of *mgrB* (colistin resistance), and frameshift mutations in *ompK36* (β-lactam resistance) likely selected by antibiotic usage. Comparison with publicly available genome sequences and literature review revealed no sign of dissemination of this CPKp strain. However, the VIM-1 plasmid was found in diverse Enterobacterales species, although restricted to Spain. One isolate became urease negative following *IS*5075 transposition into *ureC*. Analysis of 9,755 *K. pneumoniae* genomes showed the same *ureC*:*IS*5075 insertion in 14.1% of the isolates and explained why urease activity is a variable identification trait for *K. pneumoniae*. Transposition into *ureC* results from the similarity of its 3’ end and the terminal inverted repeats of Tn21-like transposons, the targets of *IS*5075 and related insertion sequences (ISs). As these transposons frequently carry ARGs, this might explain the frequent chromosomal invasion by these ISs and *ureC* inactivation in multidrug-resistant isolates.

IMPORTANCE Evolution of multidrug-resistant bacterial pathogens occurs at multiple scales, in the patient, locally in the hospital, or more globally. Some mutations or gene acquisitions, for instance in response to antibiotic treatment, may be restricted to a single patient due to their high fitness cost. However, some events are more general. By analyzing the evolution of a hospital-acquired multidrug-resistant *K. pneumoniae* strain producing the carbapenemase VIM-1, we showed a likely environmental source in the hospital and identified mutations contributing to a further decrease in antibiotic susceptibility. By combining the genomic analysis of this outbreak with literature data and genome sequences available in databases, we showed that the VIM-1 plasmid has been acquired by different Enterobacterales but is endemic only in Spain. We also discovered that urease loss in *K. pneumoniae* results from the specific transposition of an IS element into the *ureC* gene and was more frequent in fluoroquinolone-resistant isolates and those carrying a carbapenemase gene.

**KEYWORDS** carbapenemase, insertion sequence, *Klebsiella pneumoniae*, drug resistance evolution, mobile genetic elements, urease

*Klebsiella pneumoniae* is responsible for a broad range of diseases including pneumonia and bloodstream and urinary tract infections, mostly in health care facilities. *K. pneumoniae* isolates are frequently resistant to multiple antibiotics and contribute to the dissemination of antibiotic resistance genes (ARGs) (1, 2). Carbapenems are among the last-resort drugs to treat infections due to multidrug-resistant (MDR) *Enterobacterales*, including *K. pneumoniae* isolates expressing extended-spectrum β-lactamases (ESBLs). From the end of the 20th century onward, the emergence and dissemination of carbapenemase-producing *K. pneumoniae* (CP*Kp*) resulting in high mortality rates have become a major public health threat. CP*Kp* hospital outbreaks are particularly feared due to potential patient-to-patient transmission or transmission from the hospital environment to the patient. Recently, a broad genomic study on CP*Kp* from 244 hospitals in 32 countries across Europe confirmed the existence of dominant lineages responsible for hospital outbreaks (3). In this study, the most prevalent multilocus sequence typing (MLST) types (STs) were from the clonal group (CG) 258, including ST258, -512, -340, -437, and -11, expressing the carbapenemase KPC (1, 3). Other prominent CP*Kp* STs are ST307 (4) and ST101 (5). However, the molecular epidemiology of CP*Kp* is different between countries (6), and a large proportion of CP*Kp* isolates belongs to diverse and rare STs denoting relevance of local epidemiology.

In 2007, we reported the first case of a hospital outbreak involving CP*Kp* isolates producing the VIM-1 carbapenemase in a hospital in Madrid, Spain (7, 8). During the same period, *Escherichia coli*, *Klebsiella oxytoca*, and *Enterobacter cloacae* isolates also producing VIM-1 were identified in the same hospital (7). Pulsed-field gel electrophoresis (PFGE) of *K. pneumoniae* isolates showed that they were likely clonal (8). This observation raised questions about the risk of endemicity of this clone and of the plasmid carrying bla*VIM-1* (7).

Whole-genome sequencing (WGS) is becoming instrumental to decipher hospital outbreaks and to characterize transmission (9). Point mutations and small indels, particularly those leading to gene inactivation or contributing to antibiotic resistance, are the main focus of genomic epidemiology studies. Other events, and in particular the mobility of insertion sequences (ISs), more difficult to identify by short-read sequencing, are frequently set aside. In this work, we have analyzed the evolution of the VIM-1-producing *K. pneumoniae* isolates from the outbreak (7, 8). In addition to mutations selected by antibiotics used in the hospital, we observed a diversity in ARGs and plasmid contents and mobility of transposable elements: a group 2 intron and three ISs, IS26, IS5075, and IS421. In one isolate, IS5075 transposed into the ure operon encoding the urease subunits and led to a urease-defective phenotype. By analyzing 9,755 publicly available *K. pneumoniae* genome sequences, we show that this insertion is frequent, explaining why some *K. pneumoniae* isolates display a urease-negative phenotype. Furthermore, through a literature survey and the analysis of publicly available genome sequences, we did not find any evidence of further dissemination of this VIM-1-producing strain. On the other hand, the bla*VIM-1* plasmid has broadly disseminated across *Enterobacterales* species but so far has been isolated only in Spain.

**RESULTS**

Genomic characterization of the outbreak isolates. Illumina WGS of the 18 isolates and in silico MLST showed that the first 17 isolates (KP*VIM-1* to -17) sharing the same PFGE profile belong to ST39 and the last isolate (KP*VIM-18*) belongs to ST45 (see Table S1 in the supplemental material). ST45 represents 1.5% (n = 161) of the 10,515 genomes retrieved from NCBI (July 2020). ST39 is less frequent, with only 38 other genome sequences, including seven isolates carrying carbapenemase genes (bla*KPC-3*, n = 3; bla*KPC-2*, n = 2; bla*NDM-1*, n = 2) but none carrying bla*VIM-1*. In order to characterize the strain responsible for the outbreak and to identify genetic events occurring during its
evolution, we determined the complete genome sequence of the first isolate, KPVIM1. The KPVIM1 chromosome is 5,351,626 bp long. It hosts four plasmids of 227,556 bp (pKP1-1), 110,924 bp (pKP1-2), 76,065 bp (pKP1-3), and 80,027 bp (pKP1-4) (Table S2). The chromosome and plasmids pKP1-1, -2, and -3 carry 31 ARGs, including three in two copies \( \text{msr}(E), \text{mph}(E), \text{sulI} \) (Table S2). Those ARGs target all major classes of antibiotics used against Gram-negative bacteria. The porin gene \( \text{ompK}35 \) is interrupted by a nonsense mutation at codon 230. In agreement with the ARG content, KPVIM1 is highly resistant to almost all antibiotics tested, remaining susceptible to only ciprofloxacin, tigecycline, imipenem, and colistin and exhibiting an intermediate phenotype to amikacin, nalidixic acid, meropenem, and ertapenem (Fig. S1).

The \( \text{bla}_{\text{VIM-1}} \) gene is carried by a gene cassette inserted in a type 1 integron expressing six ARGs in addition to \( \text{bla}_{\text{VIM-1}}, \text{aacA4}, \text{dfrB1}, \text{ant1}, \text{cat}, \text{emrE}, \) and \( \text{folP} \) (Fig. 1). BLASTN search using the nucleotide sequence of this plasmid against the contigs of KPVIM18 showed 100% identity over its entire length, except a 1,722-bp region containing a \( \text{catA} \) gene and missing in KPVIM18. The \( \text{VIM-1} \) plasmid was therefore likely transferred in the hospital from the outbreak strain to the ST45 \( \text{K. pneumoniae} \) isolate. Plasmid pKP1-3 belongs to the IncL/M type. Comparison with complete plasmid sequences showed that pKP1-3 is more than 99.9% identical over 89% of its length to pKP1050-3b carrying \( \text{bla}_{\text{VIM-1}} \) from a pan-drug-resistant \( \text{K. pneumoniae} \) strain isolated in June 2016 in a hospital in Madrid (Fig. 1) (10). Both plasmids are highly similar to a \( \text{bla}_{\text{VIM-1}} \)-carrying plasmid from a \( \text{Salmonella enterica} \) serovar Typhimurium strain isolated in Spain in 2014 (11) and from \( \text{Klebsiella oxytoca} \) strains isolated in Madrid in 2016 (12). Recently, a closely related plasmid was identified in 28 \( \text{Serratia marcescens} \) \( \text{VIM-1} \)-producing isolates recovered in our hospital as KPVIM1 between September 2016 and December 2018 (13). We identified by BLASTN search 10 additional \( \text{K. pneumoniae} \)
isolates carrying a plasmid closely related to pKP1-3, among the 85 K. pneumoniae genome sequences containing blaVIM-1 of the 10,515 K. pneumoniae genome sequences from the NCBI (Table S3). Strikingly, these isolates from four different STs were also all isolated in Spain between 2010 and 2016. Therefore, IncL/M plasmids carrying blaVIM-1 likely arose in Spain following the insertion of a type 2 integron and disseminated locally only but were recurrently isolated in Spain between 2005 and 2018.

These plasmids are closely related to the broadly distributed IncL/M plasmid pOXA48 carrying the blaOXA-48 carbapenemase gene (10) (Fig. 1). pKP1-3 shows only seven single nucleotide polymorphisms (SNPs) over 57,386 conserved bp with pOXA-48_1639, the closest relative identified at the NCBI (accession number LR025105.1). BLASTN search against the NCBI database showed that one SNP was specific to all characterized IncL/M VIM-1 plasmids, whereas for the six other positions, two different allelic forms could be identified: one shared by pOXA-48_1639 and other pOXA-48 plasmids, the other by pKP1-3 and IncL/M plasmids carrying other resistance genes. Therefore, these two plasmids share a very recent common ancestor which acquired either Tn1999 (14) carrying blaOXA-48 or an integron carrying blaVIM-1.

**Intrahospital evolution of the ST39 lineage follows different paths associated with modifications of antibiotic susceptibility.** On the basis of the variants identified, we reconstructed the evolutionary path of the 17 ST39 isolates (Fig. 2A). In total, we identified 64 SNPs (59 in the chromosome and five in the plasmids) and seven short indels, five of them leading to a frameshift in coding frames (Table S4). Ancestral genotype for each polymorphism was predicted by parsimony based on BLASTN comparisons with complete K. pneumoniae genome sequences at the NCBI. The first isolate, KPvim1, shows six SNPs compared to the reconstructed sequence of the last common ancestor (LCA) of the 17 isolates. We next analyzed the root to tip number of chromosomal SNPs according to the time of isolation. Despite the duration of the outbreak over 24 months, we did not observe a strong temporal correlation (Fig. 2B).

We identified three large chromosomal deletions: a 6.3-kb deletion encompassing mgrB, a 600-bp deletion of a type 6 secretion system (T6SS) immunity phospholipase A1-binding lipoprotein, and a 55.4-kb deletion corresponding to the excision of an integrated and conjugative element. Five large deletions in pKP1-1 and pKP1-2 led to
the loss of clusters of ARGs (Table S2 and S4) in agreement with modifications of the antibiotic susceptibility profiles (Fig. S1).

Several genetic events were likely selected in response to antibiotic use in the hospital. The deletion of the mgrB gene led to colistin resistance in KPvM17 (Fig. S1). The same isolate was highly resistant to all β-lactams including carbapenems due to the inactivation of the second major porin gene, ompK36, by a nonsense mutation leading to a stop codon at position 125. In addition, we identified three mutations disrupting ooxR and ramR genes encoding repressors of efflux systems. ooxR was inactivated by an IS26 insertion in KPvM12 and KPvM13, whereas ramR was inactivated by a nonsense mutation in KPvM14 and by a frameshift mutation in KPvM7 and KPvM8. In agreement with previous comparisons of mutants of ooxR and ramR (15–18), we observed a stronger decrease in the susceptibility to fluoroquinolones in the isolates mutated in ooxR (KPvM12 and KPvM13) and a stronger decrease in tigecycline susceptibility in the isolates mutated in ramR (KPvM7, -8, and -14). In the case of KPvM14, the mutation in ramR likely compensates the loss of the qnrA1 gene for fluoroquinolone susceptibility. The five isolates also showed a decreased susceptibility to cefepime and cefoxitin (Fig. S1).

To assess if there was any fitness cost associated with the increased resistance observed, we followed bacterial growth of these isolates in LB at 37°C. We observed in all four mutated isolates a decreased growth rate compared to KPvM1. The effect was more pronounced for KPvM17 defective in both mgrB and ompK36, which showed a 17% increase of generation time (Fig. 3).

Diversity of cryptic plasmid content. In the course of the epidemic strain evolution, we also observed changes in plasmid content (Fig. 2). Plasmid pKP1-4 is a IncFII type, which is present in the first isolate, KPvM1, and in three of the last isolates of the outbreak (KPvM11, -16, and -17), reflecting its stability. This plasmid mainly codes for maintenance functions (toxin-antitoxin systems, colicin B production, and partition) and conjugative functions. BLASTN search against bacterial genome sequences showed that pKP1-4 is almost identical (99.7% identities over its entire length) to plasmid pEC14III (accession number KU932028.1) from an E. coli strain isolated in Finland. We also identified three plasmids specific to the lineage KPvM3 to KPvM8 (Fig. 2). These six isolates share a 34,017-bp-long, linear plasmid (pKP3-5) flanked by two 695-bp-long terminal inverted repeats (TIRs). Unlike most linear plasmids described in K. pneumoniae, pKP3-5 is unrelated to phages. No adaptive functions were recognized, unlike in a
similar linear plasmid, pBSSB1 from *Salmonella enterica* serovar Typhi, that encodes a flagellin structural gene (19). A search among *K. pneumoniae* genomes revealed 19 isolates carrying putative linear plasmids closely similar to pKP3-5 (>90% identities over 90% of the length). The two other plasmids are small high-copy-number plasmids, pKP3-6 (2,811 bp) and pKP3-7 (3,861 bp), that are present in strains KPVIM3 to -6 and KPVIM3 to -8, respectively (Fig. 2 and Table S2). No adaptive functions were predicted in these two plasmids. For these three plasmids, we could not determine whether they were gained in the common ancestor of the KPVIM3 to KPVIM8 clade or lost by other isolates.

**Insertion of IS5075 into ureC is responsible for a urease-negative phenotype in one isolate of the outbreak.** In addition to IS26 insertion in *oqxA*, we identified nine transpositions of mobile genetic elements: two insertions of a class 2 intron named Klpn.15 (20) and two and five transpositions of IS421 and IS5075, respectively (Fig. 2). Compared to the other isolates, KP

**Urease-negative phenotypes are prevailing in several *K. pneumoniae* MDR lineages.** Urea hydrolysis is an identification trait of *K. pneumoniae* in clinical microbiology laboratories. However, earlier reports have shown that 5% of *K. pneumoniae* isolates are urease negative (23). In order to determine whether this phenotype was due to similar IS5075 transposition, we analyzed the *ureC* gene in 9,755 *K. pneumoniae* genomes quality filtered from the 10,515 genome sequences retrieved from the NCBI (Table S5). BLASTN search showed that an IS5075 or a similar IS was inserted at the same position in 1,380 isolates (14.1%) (Table 1). A search for other insertions or

*After filtering out 760 genome sequences out of the 10,515 sequences retrieved from the NCBI.

**Percentage of isolates with an IS insertion in ureC.

*Percentage of ureC WT isolates mutated in ORDR and/or carrier of carbapenemase genes.

*Percentage of ureC::ISS075 isolates mutated in ORDR and/or carrier of carbapenemase genes.

*Significance of the difference between ureC::ISS075 and ureC as determined by the chi-square or the Wilcoxon rank sum statistical test.

framenshifts in ureC did not reveal other frequent mutations putatively responsible for a urease deficiency.

To determine whether the insertion of ISS075 into ureC preferentially occurred under specific genetic backgrounds, we analyzed the 45 K. pneumoniae STs with at least 20 isolates (Fig. 5). We observed that ISS075 urease inactivation occurred throughout the species with variable frequencies. In seven STs, all with fewer than 100 isolates, no insertion was observed. On the other hand, we observed a high proportion of ureC::ISS075 isolates in some STs like ST11 (884 out of 1,603) and ST340 (18 out of 77 isolates). As several of the STs associated with a higher frequency of ureC::ISS075 include major MDR lineages, we next analyzed the distribution of insertion frequencies in ureC in relation to antibiotic resistance. As markers of antibiotic resistance, we considered mutations in fluoroquinolone resistance (FQR) determinants, presence of carbapenemase genes, and the number of ARGs among the 9,755 K. pneumoniae genome sequences (Table S5). Among these genome sequences, 62% were mutated in gyrA and/or parC quinolone resistance-determining regions (QRDRs), 53% carried carbapenemase genes, and the average number of ARGs was 9.33, revealing a strong bias toward MDR isolates (Table 1). Despite this bias, ureC::ISS075 isolates appeared as even more resistant, with an average number of 12.5 ARGs compared to 8.8 in the remaining isolates, 94% of the isolates showing mutations in gyrA and/or parC and 86.4% carrying a carbapenemase gene (Table 1). To determine whether the insertion in ureC was associated with a global expansion of ISS075 and related Is, we estimated the copy number of these Is in the different isolates (Table 1). Isolates with an IS insertion in ureC showed on average a 4-fold-higher copy number of ISS075 and related Is than the remaining isolates (5 versus 1.31). On the other hand, more than half of the isolates with an intact ureC gene did not carry a single ISS075 copy (4,334 out of 8,375).

In a given ST, a high frequency of ureC::ISS075 isolates might result from frequent transposition events or from the expansion of lineages carrying the insertion. To discriminate between these two possibilities, we performed a whole-genome phylogeny focusing on ST11, ST14, and ST258. ST11 was the most abundant ST among the genome sequences retrieved from the NCBI (16.4% of all isolates). Except two isolates

May/June 2021 Volume 6 Issue 3 e00244-21
that were wild type (WT) for gyrA and parC, all ST11 isolates were predicted to be FQR (Fig. 6). The two most populated lineages belong to the K-types KL64 \((n = 622)\) and KL47 \((n = 463)\). These closely related lineages share the same three mutations in QRDRs (ParC-80I, GyrA-83I, GyrA-87G) and carry the carbapenemase gene \(\text{bla}_{KPC-2}\). Analysis of IS5075 insertions in \(\text{ureC}\) showed an uneven distribution, mostly associated with these two lineages. In the KL64 clade, the IS insertion is ancestral, as it was present in all except six isolates (in pink). In the KL47 clade, two different situations were noted: an ancestral transposition event in the LCA of a specific sublineage, with the 138 isolates from this clade showing an IS5075 in \(\text{ureC}\) (clade colored in red), and a relatively high frequency of insertion in the other isolates of the clade (85 out of 324, 26%) likely
resulting from multiple sporadic transposition events. Out of the two clades, the frequency of insertion is much lower (8.5%). All over the ST11 phylogeny, insertion in ureC gene was associated with a higher copy number of IS5075 with an average of 5 copies compared to 1.7 in ST11 isolates with a WT ureC gene. Altogether, these results show that the high proportion of ST11 isolates mutated in ureC results in a large part from the dissemination of two clades showing a high number of IS5075 copies. The situation was similar among ST14 isolates, as all but one isolate (n = 58) mutated in ureC belonged to a single FQR lineage, suggesting that transposition occurred in the LCA of the lineage (in blue, Fig. S2). Isolates of this lineage also showed a high IS5075 copy number (n = 5.1). In ST258, isolates were characterized by a lower frequency of IS insertion in ureC (6.9%). Most of the ST258 isolates cluster in two lineages expressing two different capsule operons of K-types KL106 and KL107 and associated mostly with the carbapenemase genes blaKPC-2 and blaKPC-3, respectively (24). In contrast to what was observed in ST11 and ST14, no expansion of a large ureC::IS5075 clade occurred.
(Fig. S3). All but two isolates with the insertion in ureC belonged to the KL107 lineage. Strikingly, this clade was characterized by a higher copy number of IS5075 of 2.17 (5.24 for ureC::IS5075 isolates) compared to only 0.12 for the KL106 lineage. Therefore, a major driver for insertion into ureC is the presence of an IS5075 or a related IS and its active transposition.

DISCUSSION

Whole-genome sequencing has revolutionized molecular epidemiology, and its use in outbreak analysis has contributed to deciphering the path of pathogen transmission (25). Here, we investigated the first outbreak due to a VIM-1-producing K. pneumoniae strain in Spain (7, 8). The strain was extensively drug resistant and belongs to an uncommon ST (ST39). Based on available genomic data, we showed that the strain preexisted in the hospital prior to the identification of the first isolate in October 2005. Furthermore, the weak temporal signal in the evolution (Fig. 2B) indicated a likely environmental reservoir in the hospital, which agrees with epidemiological data (7). Molecular clocks for K. pneumoniae evolution have been estimated between 1.4 (26), 1.9 (27), and 3.65 (28) mutations/10^6 bp/year. Here, the rate of SNPs/10^6 bp/year is in the lower range (n = 0.87). Growth as a biofilm compared to planktonic growth has been related to a greater diversity due to its structured organization but a lower mutation rate due to a reduced number of generations (29). The diversity observed, the duration of the outbreak, and the small number of SNPs agree with a biofilm source of the isolates. In line with this observation, we observed biofilm production of all the isolates but to variable levels (see Fig. S4 in the supplemental material).

During the 2-year evolution of the strain, we observed variations in the antibiotic resistance profile. This was due on the one hand to the loss of ARGs (Table S4). On the other hand, mutations leading to the increased expression of efflux pumps or to a decreased drug permeation, and subsequently to a decreased susceptibility to some antibiotics, were selected. However, these mutations led to a fitness cost (Fig. 3), which might explain their limited expansion in the hospital.

By combining genomic analysis of the strain responsible for the outbreak with global genomic information retrieved from the NCBI and data from the literature, we were able to draw more general conclusions related to the risk associated with the outbreak strain and the VIM-1 plasmid. Likewise, we were able to identify the main reason for urease deficiency among K. pneumoniae isolates. Following the identification of the first VIM-1 isolates in Spain, their dissemination was a matter of concern (7). Although we showed that one single ST39 clone, except for one isolate, was responsible for the outbreak, we did not identify any new occurrence of this strain or of an ST39 isolate carrying blaVIM-1, based on bibliographical survey and on the analysis of more than 10,000 publicly available K. pneumoniae genome sequences. Therefore, this clone seems to be restricted to the hospital where it was isolated. Conversely, we showed that the plasmid carrying blaVIM-1 has disseminated among various Enterobacterales species. Transfers occurred probably in the hospital context, as suggested in the case of an S. Typhimurium isolate (11). Similarly, we showed the transmission of the VIM-1 plasmid between K. pneumoniae isolates in the course of the outbreak. We previously predicted similar transfers between K. pneumoniae and E. coli based on plasmid typing and size determination (7). This IncL/M plasmid is closely related to the broadly disseminated pOXA48. Our mutation analysis strongly suggests independent gain of a carbapenemase gene by very similar plasmid backbones showing only seven SNPs over 57,868 bp. In agreement with this hypothesis, the first OXA-48 plasmid was detected in Spain in 2009 (30), 4 years after the first VIM-1 isolate of the hospital outbreak (7).

Strikingly, until now only IncL/M VIM-1 plasmids were reported in Spain. A recent study on plasmids encoding VIM-1 from broad origins showed that among the 28 plasmids analyzed, nine were from IncL/M type (31). These nine plasmids were related to pKP1-3 and were from K. pneumoniae, Enterobacter hormaechei, and E. cloacae and all from Spain. The limited dissemination of the VIM-1 plasmid might be due to the
conjunction of different factors including: a lower conjugation efficiency than pOXA-48 plasmids, a fitness cost restricting its dissemination to environments characterized by strong selective pressures, such as the hospital, or a specificity in antibiotic prescription in Spain. Comparing IncL/M VIM-1 and OXA-48 plasmids provides a model system to study two closely related plasmids with two different spreading destinies.

Urease is considered in many bacterial species as a virulence factor beyond its contribution in harnessing urea as a nitrogen source (32). Urease participates in the adaptation to acidic conditions in a broad range of human pathogens, including Helicobacter pylori (33), Yersinia enterocolitica (34), and Proteus mirabilis (35). Urease is considered a potential target for the development of new antibacterial drugs against enteric bacteria including K. pneumoniae (36). In K. pneumoniae, the urease has been shown to contribute to gastrointestinal colonization (37). However, a significant proportion of K. pneumoniae isolates are urease negative. Here, we showed that the inactivation of the operon is due to the transposition into the ureC gene of ISS075 or of related ISs, like IS4321, sharing the same specificity. Urease inactivation can be observed in both carriage isolates and isolates associated with clinical symptoms. For instance, we identified a cluster of eight ISS075:ureC ST340 isolates from a single institution (Fig. S5). These isolates were recovered from three patients, from urinary tract infections, blood culture, cerebrospinal fluid, and fecal carriage (38).

Among ureC::ISS075 isolates, we observed a higher prevalence of gyrA and parC mutations and of carbapenemase genes and, more generally, a higher number of ARGs compared to ureC WT isolates (Table 1). This was partly due to a small number of MDR lineages mutated in ureC, such as those of ST11 and ST14, which represent 68% of the ureC::ISS075 isolates (Fig. 6 and Fig. S2). Nevertheless, this higher prevalence remained true even after removing ST11 and ST14 isolates (Table 1). IS insertions in ureC were also associated with a 4-fold increase in ISS075 copies, resulting from additional transposition events (Table 1). This expansion of ISS075 in some genetic backgrounds might be a relatively recent event. Indeed, 44% of the isolates did not carry a single ISS075 copy, despite the high number of ARGs in the genomes we have analyzed. Indeed, the most frequent targets of ISS075 are the conserved TIR of transposons related to Tn21, which are ARG vectors and frequently carried by conjugative plasmids as in the case of pKP1-2 (21, 22). This insertion specificity represents a safe harbor for these ISs, as it does not incur fitness costs and ensures their dissemination. The insertion into ureC results from the high similarity between its last codons and TIRs of Tn21 and is likely accidental. Therefore, the higher frequency of ureC inactivation in some MDR lineages might merely be a consequence of a more frequent acquisition of Tn3 family transposons carrying ISS075. However, we cannot completely dismiss the possibility that the loss of urease activity might provide MDR K. pneumoniae isolates with a selective advantage under some circumstances. This seems rather unlikely, as other ureC inactivation events, including transpositions of other ISs, would have been expected in that case and we did not detect such events. Overall, ISS075 transposition into the K. pneumoniae ureC gene represents a perfect example of chromosomal colonization by IS elements carried by plasmids and leading to a homoplasic loss of function.

**MATERIALS AND METHODS**

**Bacterial strains, growth conditions, and antibiotic susceptibility testing.** VIM-1-producing K. pneumoniae isolates were collected from 2005 through 2008 at Ramon y Cajal University Hospital in Madrid, Spain (8) (see Table S1 in the supplemental material). The colistin MIC was determined in Mueller-Hinton (MH) broth as recommended by the Clinical and Laboratory Standards Institute (CLSI) guidelines (39). Susceptibility to 33 other antibiotics (Fig. S1) was evaluated by disk diffusion on MH agar according to the CLSI guidelines (39). Fitness was determined by growth curve analysis with a Tecan Infinite M200 automatic spectrophotometer during 24 h in LB. Wells were inoculated with overnight cultures at an optical density at 600 nm (OD₆₀₀) of 0.001. OD₆₀₀ was measured every 10 min. Background was determined as the average value of the OD₆₀₀ of the first three time points. Doubling time was determined between OD₆₀₀ of 0.005 and 0.03, where an almost perfect fit with an exponential growth was observed.
**Genome sequencing and sequence analysis.** *K. pneumoniae* genomes were sequenced by using the Illumina HiSeq2500 platform, with 100-nucleotide (nt) paired-end reads. Libraries were constructed by using the Nextera XT kit (Illumina). Reads were assembled with SPAdes 3.9.0 (40). The complete genome sequence of strain KP

\( ^{\text{\textregistered}} \) was determined by using the long-read PacBio technology (Macrogen, Seoul, South Korea). Reads were assembled with the RS_HGAP_Assembly.3 protocol (41) and with Canu (42). The consensus sequence was polished with Quiver (41) and manually corrected by mapping Illumina reads with B sensed pas 03.2 (43). Variants compared to KP

\( ^{\text{\textregistered}} \) were identified by using Breseq (43). Genome sequences were annotated with Prokka 1.14.5 (44) and analyzed for MLST and ARG content by using Kleborate (45) and ResFinder 4.0.1 (46). Plasmid incompatibility groups were identified by using PlasmidFinder 2.1 (47). Directionality of mutations was determined as previously described by performing BLASTN comparisons against publicly available *K. pneumoniae* genomes (48).

**Analysis of publicly available genome sequences.** *K. pneumoniae* genome assemblies (n = 10,515) were downloaded from the NCBI (July 2020) with Batch Entrez (49). Genome sequences with more than 200 contigs of more than 500 nt were filtered out. Sixty genome sequences (BioProject PRJNAS10003) for which the contig ends corresponding to repeated sequences have been trimmed were removed from the analysis. In total, we analyzed IS5075 insertions in 9,755 genome sequences (Table S5). Phylogenetic analysis was performed by using Parsnp 1.1.2 (50). Recombination regions were visually identified as regions with a higher SNP density by using Gingr (50) and removed from the reference genome sequence (ST11, strain FDAARGOS_444, CP023941.1; ST14, strain 11, CP016923.1; ST258, strain BIC-1, NZ, CP022573.1; ST340, strain EuSCAPE_RS081, GCA_902155965.1_18858_1_51). Insertion of IS5075 and of related ISs in ureC was identified by BLASTN search using as query sequence the junction sequence detected in the KP

\( ^{\text{\textregistered}} \) isolate encompassing 20 nt of the ureC gene and 20 nt of IS5075 (E value of 1e−10 as threshold). The integrity of ureC was tested by tBLASTn using the UreC protein sequence from KP

\( ^{\text{\textregistered}} \) as query. Copy number of IS5075 and of closely related ISs was estimated by counting BLASTN hits (100% identity over the entire length), using the first 17 nucleotides of the IS5075 sequence as query. Phylogenetic trees were visualized by using iTOL (51).

**Phenotypic analyses.** The urease detection test was carried out with urea-indole medium (Bio-Rad) according to the manufacturer’s instructions. Biofilm formation capacity was measured by the microtitre plate assay as previously described (52). *K. pneumoniae* strain LM21 (53) was used as a positive control.

**Statistical analysis.** The significance of the differences in frequencies of IS insertions in ureC was determined by using the chi-square test. The significance of differences in IS5075 copy numbers and in ARG numbers was determined by the Wilcoxon rank sum test. Both tests were performed by using standard libraries contained within the R statistics package (http://www.R-project.org/). Statistical significances of growth rate differences were tested with a Student t test.

**Availability of data.** All sequence data have been deposited at DDBJ/EMBL/GenBank (BioProject PRJEB41835) with the following accession numbers: LR991401, KP

\( ^{\text{\textregistered}} \) chromosome and plasmids; LR991487, plasmid pKP1-5; LR991544, plasmid pKP1-6; LR991565, plasmid pKP1-7. BioSample identifiers for the Illumina sequence data are listed in Table S1.
