Abstract

We study an optimal control problem arising from a generalization of rock-paper-scissors in which the number of strategies may be selected from any positive odd number greater than 1 and in which the payoff to the winner is controlled by a control variable $\gamma$. Using the replicator dynamics as the equations of motion, we show that a quasi-linearization of the problem admits a special optimal control form in which explicit dynamics for the controller can be identified. We show that all optimal controls must satisfy a specific second order differential equation parameterized by the number of strategies in the game. We show that as the number of strategies increases, a limiting case admits a closed form for the open-loop optimal control. In performing our analysis we show necessary conditions on an optimal control problem that allow this analytic approach to function.

Keywords: Cyclic Game, Evolutionary Game Theory, Optimal Control, Lie Bracket

1. Introduction

Cyclic competition occurs frequently in nature \cite{1,2,3,4,5,6,7}. Cyclic competition in coral reef populations are studied in \cite{1}. Sinervo and Lively first characterized rock-paper-scissors like competition in lizards \cite{2}, while

Gilg, Hanski and Sittler [4] study this behavior in rodents. Cyclic behavior in microbial populations is studied in [3, 5, 6, 7]. In classical and evolutionary game theory, cyclic dominance (e.g., matching pennies, rock-paper-scissors) games are commonly studied [8, 9]. Biologically speaking, in an idealized cyclic game, the absolute fitness measure (payoff) resulting from species interaction can be represented by a circulant matrix, in which row \( k \) is a rotation of row \( k - 1 \) for each \( k \). Games with circulant payoff matrices have been studied extensively in evolutionary game theory [10, 11, 12, 13, 14, 15, 16, 17] and provide some of the most interesting behaviors [16].

In early work, cyclic interaction is considered without explicit reference to games. Cyclic (chemo-biological) interactions are studied extensively in [18, 19, 20] in which both competitive and cooperative behaviors are identified. Analysis of the replicator in which a circulant matrix emerges is studied in [11] as a result of cyclic mass interaction kinetics. Zeeman [10] made an early study of the dynamics of cyclic games showing that in rock-paper-scissors a degenerate Hopf bifurcation leads to the emergence of a non-linear center with no limit cycle possible in any 3 strategy game under the replicator dynamics. Since this early work, several authors have investigated various cyclic games and games characterized by circulant matrices. Among many other works: Hofbauer and Schlag [15] consider imitation in cyclic games; Diekmann and Gils specifically study the cyclic replicator dynamics and focus on the properties of low-dimensional cyclic games [14]; Ermentrout et al. consider a transition matrix evolutionary dynamic in which a limit cycle emerges in the rock-paper-scissors game [21]; and Griffin and Belmonte [22] study a triple public goods game and show that is is diffeomorphic to generalized rock-paper-scissors. Each of these works focuses explicitly on classes of circulant games, while recent work by Granić and Kerns [17] characterizes the Nash equilibria of arbitrary circulant games, but does not focus on the evolutionary game context.

There has also been extensive work on spatial games with circulant payoff matrices. Peltomäki and Alvara [23] consider both 3 and 4 state rock-paper-scissors. Other papers consider rock-paper-scissors with variations on reaction rate [24] or study the basins of attraction [25]. DeForest and Belmonte [26] study a fitness gradient variation on the spatial replicator and show rock-paper-scissors can exhibit spatial chaos under these dynamics. Finally more recent work by Szczyesny et. al [27] considers spiral formations in rock-paper-scissors.

In this paper, we extend work in [22] by studying an optimal control prob-
lem defined on a $N$-strategy ($N = 3, 5, 7, \ldots$) generalization of rock-paper-scissors. Odd cardinality interactions are interesting because they model specific biological cases [2, 4, 18, 19, 20]. Additionally, when $N$ is very large, these have the potential to model systems in which individuals a variety of individuals with strengths and weaknesses interact.

In particular, the payoff matrix is (i) defined by the sum of two circulant matrices, and (ii) admits a single control parameter. Thus we consider the general class of control problems first studied in a specific case in [22]. Our payoff matrix is inspired by the generalized rock-paper-scissors matrix defined in [9]. Since every pair of heterogeneous strategic interactions (e.g., rock vs. scissors) results in a non-zero payoff, we refer to this class of games as complete odd circulant games.

The major results of this paper are:

1. We show that the complete odd circulant games admit only a unique interior fixed point under the replicator dynamics. We also characterize the fixed points of the $N$-strategy complete odd circulant game in terms of the fixed points of the $M < N$ complete odd circulant games.

2. We show that the replicator dynamics can be written as the sum of an uncontrolled component and a controlled component both of which have circulant Jacobian matrices.

3. As a consequence, we completely characterize the stability of the interior fixed point and use this to define an optimal control problem with objective to drive the system trajectories toward this interior fixed point.

4. We describe the properties of a general class of control problems with a vanishing Lie Bracket that will be used to analyze the control problem we define. This suggests interesting geometric and algebraic connections between evolutionary games and optimal control theory. As a by-product, we generalize recent control theoretic results in [28].

5. We show that a quasi-linearization of the control problem (as done in [22]) has special form admitting a complete characterization of the dynamics of the optimal control. We also derive a sufficient condition on control optimality and thus completely generalize the results in [22] to arbitrary complete odd circulant games.

6. As a part of the generalization, we find a limiting second order ordinary differential equation (as $N$ grows large) that the optimal control must obey and show that it has a natural closed form solution.
The remainder of this paper is organized as follows: In Section 2 we present preliminary results and notation. In Section 3 we introduce the control problem of interest and study a general class of optimal control problems that will assist in the derivation of our main results. Our main results on control of complete odd circulant games are found in Section 4. Conclusions and future directions are presented in Section 5.

2. Notation and Preliminary Results

A circulant matrix is a square matrix with form:

\[
A = \begin{bmatrix}
a_0 & a_{n-1} & a_{n-2} & \cdots & a_1 \\
a_1 & a_0 & a_{n-1} & \cdots & a_2 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
a_{n-1} & a_{n-2} & a_{n-3} & \cdots & a_0
\end{bmatrix}.
\]

A circulant matrix is entirely characterized by its first row and all other rows are cyclic permutations of this first row. The set of \(N \times N\) circulant matrices forms a commutative algebra, a fact that will be used frequently in this paper. Moreover, the eigenvalues of these matrices have special form. If \(A\) is an \(N \times N\) circulant matrix and \(\omega_0, \ldots, \omega_{N-1}\) are the \(N\)th roots of unity, then eigenvalue \(\lambda_j (j = 0, \ldots, N - 1)\) is given by the expression:

\[
\lambda_j = a_0 + a_{n-1} \omega_j + a_{n-2} \omega_j^2 + \cdots + a_1 \omega_j^{N-1}.
\]

Further details on this class of matrices is available in [29].

Let:

\[
\Delta_N = \{ u \in \mathbb{R}^N : 1^T u = 1, u \geq 0 \}
\]

be the unit \(N\)-simplex embedded in \(N\)-dimensional Euclidean space. Here \(1\) is an appropriately sized vector of 1’s and \(0\) is a zero vector.

We consider a family of control problems defined on parametrized cyclic games with \(N = 2n + 1\) strategies, where \(n = 1, 2, \ldots\). If \(i \in \{1, \ldots, N\}\) and \(j \in \mathbb{Z}\), define:

\[
\mu(k) = \begin{cases} 
k \mod N & \text{if } k \mod N \neq 0, \\
N & \text{otherwise.}
\end{cases}
\]

(1)
For the remainder of this paper, define $L_N, M_N \in \mathbb{R}^{N \times N}$ so that:

$$L_{Nij} = \begin{cases} (-1)^{\mu(N(i-1)+j-i)} & \text{if } i \neq j, \\ 0 & \text{otherwise.} \end{cases}$$

(2)

and

$$M_{Nij} = \begin{cases} 1 & \text{if } i \neq j \text{ and } (-1)^{\mu(N(i-1)+j-i)} = 1, \\ 0 & \text{otherwise.} \end{cases}$$

(3)

By way of example, we illustrate the matrices $L_5$ and $M_5$ for the 5-strategy cyclic game.

$$L_5 = \begin{bmatrix} 0 & -1 & 1 & -1 & 1 \\ 1 & 0 & -1 & 1 & -1 \\ -1 & 1 & 0 & -1 & 1 \\ 1 & -1 & 1 & 0 & -1 \\ -1 & 1 & -1 & 1 & 0 \end{bmatrix}, \quad M_5 = \begin{bmatrix} 0 & 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 \end{bmatrix}.$$

From a game-theoretic perspective, we can think of $L_N$ as being the traditional payoff matrix of the complete cyclic game with $N$ strategies; e.g., the payoff matrix of rock-paper-scissors. On the other hand, $M_N$ can be thought of an actuating matrix that will determine whether the interior fixed point of the complete cyclic game is stable or unstable, as we show in the sequel.

In the remainder of this paper, we will consider the generalized cyclic game with $N$ strategies where $N = 3, 5, 7, \ldots$, and we note that both $L_N$ and $M_N$ are circulant matrices. The payoff matrix for the generalized cyclic game with $N$ strategies and parameter $\gamma$ is:

$$A_N(\gamma) = L_N + \gamma M_N.$$  

If $\gamma = 0$ and $N = 3$, then $A_3(\gamma)$ is just the rock-paper-scissors matrix. Without loss of generality, we assume $\gamma > -1$. Otherwise, the natural winning precedence in the cyclic game is reversed.

The matrix $M_N$ is the adjacency matrix of an $N$ vertex circulant directed graph $G(M_N)$, whose edge direction determines the winning precedence between two strategies in the underlying cyclic game. This is illustrated in Figure 1. In particular, if $M_{Nij} = 1$, then Strategy $i$ defeats Strategy $j$ and yields payoff $1 + \gamma$ in $A_N(\gamma)$.
In the control problem defined in the sequel, the replicator dynamics are the nonlinear equations of motion with control parameter $\gamma$:

$$S_N = \begin{cases} \dot{u}_i = u_i \left((e_i - u)^T A_N(\gamma) u\right), \\ u(0) = u_0. \end{cases}$$ (4)

Here $u = (u_1, \ldots, u_N)$ is the vector denoting the proportion of the population playing each of the $N$ strategies. It is well known [12, 9] that if $u_0 \in \Delta_N$, then $u(t)$ is confined to $\Delta_N$ for all time. For the remainder of this paper, we assume $u_0 \in \Delta_N$.

Assume $m, n \in \{1, 2, \ldots, \}$ and let $M = 2m + 1$ and $N = 2n + 1$. The point-to-set mapping $\pi_{M,N} : \Delta_M \to 2^{\partial \Delta_N}$ maps a point $u \in \Delta_M$ to the set of points $v$ in $\partial \Delta_N$ so that:

1. $M$ elements of the vector $v$ consist of the elements of $u$. The remaining $M - N$ elements are $0$.
2. If the rows and columns of $L_N$ (resp. $M_N$) corresponding to the zero-entries in $v$ are deleted to form the matrix $\tilde{L}_N$ (resp. $\tilde{M}_N$), then $\tilde{L}_N = L_M$ (resp. $\tilde{M}_N = M_M$).

The second condition is equivalent to stating that the vertices corresponding to the non-zero strategies in $v$ induce a sub-graph of $G(M_N)$ that is isomorphic to $G(M_M)$. 
Lemma 1. Let $n \in \{1, 2, \ldots\}$ and $N = 2n + 1$, then:

1. $S_N$ has among its fixed points $e_i \in \Delta_N$ ($i = 1, \ldots, N$) and $\frac{1}{N} \mathbf{1} \in \text{int}(\Delta_N)$.
2. Furthermore, if $n > m \geq 1$, $M = 2m + 1$, and $N = 2n + 1$ and $u^+$ is a fixed point of $S_M$, then $\pi_{M,N}(u^+)$ are fixed points of $S_N$.

Proof. To prove Statement 1, note first that pure strategies are always fixed points of the replicator dynamics \cite{9}. To see that $u^* = \frac{1}{N} \mathbf{1}$ is a fixed point, note that:

$$L_Nu^* = 0,$$
$$\gamma M_Nu^* = \gamma \frac{n}{N} \mathbf{1}.$$

Consequently:

$$\gamma (u^*)^T M_N u^* = \gamma \frac{n}{N} = e_i^T M_N u^*.$$

The fact that $u^* = \frac{1}{N} \mathbf{1}$ is a fixed point follows immediately.

To prove Statement 2, suppose that $u \in \pi_{M,N}(u^+)$ for some fixed point $u^+$ of $S_M$. Let $L_N$ and $M_N$ be the square sub-matrices of $L_N$ and $M_N$ obtained by removing the rows and columns corresponding to the zero entries in $u$. By assumption, it follows at once that:

$$(e_i^T - u)^T A_N(\gamma) u = (e_i^T - u^+)^T A_M(\gamma) u^+ = 0.$$

This completes the proof. \hfill \Box

Corollary 2. The fixed point $u^* = \frac{1}{N} \mathbf{1}$ is the unique interior fixed point for $S_N$.

Proof. If $u$ is any interior fixed point, then necessarily it must satisfy the equation:

$$A_N(\gamma) u = u^T A_N(\gamma) u \cdot \mathbf{1}.$$

Note that for any $u \in \Delta_N$, $u^T L u = 0$. Therefore, $u$ must satisfy:

$$A_N(\gamma) u = \gamma \cdot u^T M_N u \cdot \mathbf{1}.$$

It is straightforward to compute:

$$u^T M_N u = \sum_{i=1}^{N} \sum_{j > i} u_i u_j.$$
We now proceed in cases. If \( \gamma = 0 \), then we solve:

\[
L_N u = 0, \\
1^T u = 1.
\]

This system has rank \( n \) with \( n \) unknowns and therefore admits a unique solution. Elementary row reduction shows that \( u^* = \frac{1}{N} 1 \) is the unique fixed point in this case.

On the other hand, if \( \gamma \neq 0 \), then let:

\[
\alpha = \sum_{i=1}^{N} \sum_{j>i} u_i u_j.
\]

We can determine a relationship between the variables by solving:

\[
A_N(\gamma) u = \alpha 1.
\]

Row-reduction on the system shows that when \( \gamma \neq 0 \) we obtain the relationship:

\[
u = \frac{\alpha}{n\gamma} 1.
\]

Consequently, \( u_1 = u_2 = \cdots = u_N \) and necessarily \( u^* = \frac{1}{N} 1 \) is again the unique interior fixed point. This completes the proof. \( \square \)

For the remainder of this paper, assume \( u^* = \frac{1}{N} 1 \) and let \( F, G : \Delta_N \rightarrow \mathbb{R}^n \) be defined component-wise as:

\[
F_i(u) = u_i ((e_i - u)L_N u), \\
G_i(u) = u_i ((e_i - u)M_N u).
\]

The replicator dynamics are then:

\[
\dot{u}_i = F(u) + \gamma G(u),
\]

which are the dynamics that will be used in the control problem of interest. We note that \( F \) and \( G \) are the functional imprints of the standard payoff matrix \( L_N \) and the actuation matrix \( M_N \) within the replicator framework.

**Lemma 3.** The Jacobian matrix of \( F \) evaluated at \( u^* = \frac{1}{N} 1 \) is:

\[
J \triangleq D_u F = \frac{1}{N} L_N.
\]
Proof. We prove the result for Row 1 of $D_u F$. The remainder of the argument follows from the circulant structure of $L_N$. We have:

$$F_1(u) = u_1 e_1^T L_N u,$$

because $u^T L_N u = 0$. Note:

$$u_1 e_1^T L_N u = u_1 \left( \sum_{j=2}^{N} (-1)^{j-1} u_j \right). \quad (8)$$

Differentiating with respect to $u_1$ and evaluating at $u_1 = u_2 = \cdots = u_n = \frac{1}{N}$ yields:

$$[D_u F]_{1,1} = \frac{1}{N} \sum_{j=2}^{N} (-1)^{j-1} = 0,$$

since $N$ is odd. Differentiating Expression 8 with respect to $u_j$ and evaluating at $u_1 = u_2 = \cdots = u_n = \frac{1}{N}$ yields:

$$[D_u F]_{1,j} = \frac{(-1)^{j-1}}{N} = \frac{1}{N} L_{N,1,j}.$$

The result now follows from the fact that $L_N$ is a circulant matrix. \qed

Lemma 4. The Jacobian matrix of $G$ evaluated at $u^* = \frac{1}{N} 1$ is:

$$H \triangleq D_u G = \frac{1}{N^2} M_N - \frac{2n}{N^2} (1_N - M_N) = \frac{1}{N^2} (N (M_N - 1_N) + 1_N),$$

where $1_N$ is an $N \times N$ matrix of 1’s.

Proof. As in the proof of Lemma 3, we show the result for Row 1 of $D_u G$. The remainder of the argument follows from the circulant structure of $M_N$. We have already noted in Corollary 2 that:

$$u^T M_N u = \sum_{i=1}^{N} \sum_{j>i} u_i u_j.$$

We compute:

$$e_1^T M_N u = \sum_{j=1}^{(N-1)/2} u_{2j+1}.$$
Differentiate with respect to $k = 2j + 1$ for $j \in \{1, \ldots, n\}$, corresponding to a non-zero index in the first row of $M_N$. We have:

$$\frac{\partial G}{\partial u_k} = u_1 \left( 1 - \left( \sum_{j \neq k} u_j \right) \right).$$

Evaluating at $u_1 = u_2 = \cdots = u_n = \frac{1}{N}$ we obtain:

$$[D_u G]_{1,k} = \frac{1}{N} \left( 1 - \frac{N - 1}{N} \right) = \frac{1}{N^2},$$

for $k = 2j + 1$ with $j \in \{1, \ldots, n\}$. Differentiate now with respect to $u_1$ to obtain:

$$\frac{\partial G}{\partial u_1} = \sum_{j=1}^{(N-1)/2} u_{2j+1} - 2 \sum_{j=2}^{N} u_1 u_j - \sum_{i=2}^{N} \sum_{j>i} u_i u_j. \quad (9)$$

Evaluating at $u_1 = u_2 = \cdots = u_n = \frac{1}{N}$ we obtain:

$$[D_u G]_{1,1} = \frac{n}{N} - 2 \frac{2n}{N^2} - \frac{1}{N^2} \left( \frac{1}{2} (N - 2)(N - 1) \right) = \frac{-N^2 - 2nN + N - 2}{N^2} = -\frac{2n}{N},$$

when $2n + 1$ is substituted for $N$ in the numerator. Finally, consider $k \neq 1$ and $k \neq 2j + 1$ for $j \in \{1, \ldots, n\}$. Differentiating with respect to $u_k$ we have:

$$\frac{\partial G}{\partial u_k} = -u_1 \left( \sum_{j \neq k} u_j \right).$$

Evaluating at $u_1 = u_2 = \cdots = u_n = \frac{1}{N}$ we obtain:

$$[D_u G]_{1,k} = -\frac{1}{N^2} (N - 1) = -\frac{2n}{N}.$$

The result now follows from the fact that $M_N$ is a circulant matrix. □

**Theorem 5.** If $\gamma > 0$, then the fixed point $u^* = \frac{1}{N} 1$ is asymptotically stable. If $\gamma < 0$, then the fixed point $u^*$ is asymptotically unstable.
Proof. From Lemmas 3 and 4 we note that the Jacobian matrix of $S_N$ at $u^*$ has the following form:

$$
\mathbf{J} = \mathbf{J} + \gamma \mathbf{H} = \frac{1}{N} \mathbf{L}_N + \gamma \left( \frac{1}{N^2} \mathbf{M}_N - \frac{2n}{N^2} \left( \mathbf{1}_N - \mathbf{M}_N \right) \right).
$$

By its construction, it is a circulant matrix with first row given by:

$$
\mathbf{J}_{1j} = \begin{cases} 
-\gamma \frac{2n}{N^2} & \text{if } j = 1, \\
-\frac{1}{N} - \gamma \frac{2n}{N^2} & \text{if } j > 1 \text{ and } j - 1 \text{ is odd}, \\
\frac{1}{N} + \gamma \frac{1}{N^2} & \text{otherwise.}
\end{cases}
$$

Letting $\omega_j$ for $j = 0, \ldots, N-1$ be the $N$th roots of unity, we know that the $j^{th}$ eigenvalue of $\mathbf{J}$ is:

$$
\sum_{k=1}^{N} \mathbf{J}_{1k} \omega_j^{k-1}.
$$

It now remains to show that the sign of the real-part of $\lambda_j$ is entirely dependent on $\gamma$. The real part of the eigenvalue is given by:

$$
\text{Re} (\lambda_j) = \sum_{k=1}^{N} \mathbf{J}_{1k} \cos \left( \frac{2\pi j (k - 1)}{N} \right).
$$

The first eigenvalue ($j = 0$) is real and readily computed:

$$
\lambda_0 = n \left( \gamma \frac{1}{N^2} - \gamma \frac{2n}{N^2} \right) - \frac{2n}{N^2} = -\gamma \frac{n(1 + 2n)}{N^2}.
$$

It is clear at once that the sign of this eigenvalue is entirely controlled by the sign of $\gamma$.

For $j > 0$, note that the periodicity of the cosine function (and the fact that the roots of unity are the vertices of the regular unit $N$-gon) implies that the coefficient of $\mathbf{J}_{1,k}$ is identical to the coefficient of $\mathbf{J}_{1,N-(k-2)}$ if $2 \leq k \leq n + 1$. From this fact and the Expression 10 the sum in Equation 11 becomes:

$$
\text{Re} (\lambda_j) = \gamma \left( \frac{-2n}{N^2} + \sum_{k=2}^{n+1} \cos \left( \frac{2\pi j (k - 1)}{N} \right) \left( \frac{1}{N^2} - \frac{2n}{N^2} \right) \right).
$$

\footnote{For details see [29]}
Factoring further we see:

\[
\text{Re} \left( \lambda_j \right) = \frac{\gamma}{N^2} \left( -2n + \sum_{k=2}^{n+1} \cos \left( \frac{2\pi j (k-1)}{N} \right) (1 - 2n) \right) = \\
\frac{\gamma}{N^2} \left( -2n + (1 - 2n) \left( \sum_{k=2}^{n+1} \cos \left( \frac{2\pi j (k-1)}{N} \right) \right) \right).
\]

The roots of unity are evenly distributed on the vertices of the unit \( N \)-gon in \( \mathbb{C} \) and therefore the sum of the real parts must be zero. It follows that:

\[
\sum_{k=2}^{n+1} \cos \left( \frac{2\pi j (k-1)}{N} \right) = -\frac{1}{2}.
\]

We now obtain an exact value for the real parts of the eigenvalues:

\[
\text{Re} \left( \lambda_j \right) = \frac{\gamma}{N^2} \left( -2n - \frac{1}{2} (1 - 2n) \right) = -\frac{\gamma}{N^2} \left( n + \frac{1}{2} \right). \tag{12}
\]

Thus we have proved that when \( \gamma > 0 \), then \( \text{Re}(\lambda_j) < 0 \) for all \( j \) and if \( \gamma < 0 \), then \( \text{Re}(\lambda_j) > 0 \). The asymptotic stability (resp. instability) of the fixed point follows immediately. \( \square \)

We illustrate the attractive interior point of the five and seven strategy cyclic games by projecting them into regular \( N \)-gons \((N = 5, 7)\), shown in Figure 2. A pure strategy corresponds to a vertex, while a mixed strategy is located in the interior. Note, these are not true trajectories as would be seen in a classic ternary plot on the three rock-paper-scissors, but they are similarly representative.

3. The Control Problem and Some General Results

We now state our control problem of interest:

\[
\mathcal{C}_N = \begin{cases} \min \int_0^{t_f} \frac{1}{2} \| u - u^* \|^2 + \frac{r}{2} \gamma^2 \ dt \\ s.t. \ \dot{u} = F(u) + \gamma G(u), \\ u(0) = u_0. \end{cases} \tag{13}
\]
Figure 2: A figure illustrating the attraction of the unique interior fixed point of the cyclic game when $\gamma = 1$ assuming 5 and 7 strategies. The trajectories are projected into regular $N$-gons ($N = 5, 7$). The closer a trajectory is to a vertex, the closer it is to that pure strategy.
where $\mathbf{u}^* = \frac{1}{N} \mathbf{1}$. Such a problem arises naturally if we consider species interacting in a cyclic manner and $\gamma$ is a costly control mechanism by which an external manager may control species populations. In [22], $\gamma$ arises naturally as a tax in a public-goods game, which is shown to be diffeomorphic to a three strategy cyclic game. As in [22], we will show that a quasi-linearization of this control problem has special structure. In this case, however, we show this special structure holds for all cyclic games (i.e., for all $N = 2n + 1$). Furthermore, we discuss the limiting behavior of the control as $N$ grows large. To do this, we first consider a very general optimal control problem and obtain necessary conditions for simplifying the Euler-Lagrange necessary conditions. We then use these simplifications to generalize the results in [22].

3.1. Control Problems with One Control and Vanishing Lie Bracket

In the remainder of this section, the functions $F, G : \mathbb{R}^n \to \mathbb{R}^n$ are arbitrary smooth functions, rather than the functions specific to the replicator dynamics for cyclic games given in Equations 6 and 7. $x \in \mathbb{R}^n$ is a state vector, and $\gamma$ is the control function to be determined.

Consider the general optimal control problem with form:

$$
\begin{align*}
\min \Psi(x(t_f)) + \int_0^{t_f} F_0(x) + \gamma G_0(x) + \frac{r}{2} \gamma^2 \, dt \\
\text{s.t. } \dot{x} = F(x) + \gamma G(x), \\
x(0) = x_0.
\end{align*}
$$

The functions $F_0, G_0 : \mathbb{R}^n \to \mathbb{R}$ are smooth. Let $r > 0, t_f$ be the terminal time, and $F_0(x)$ be convex. Expression [13] has this structure, so we are simply considering a more general case of our problem of interest.

The Euler-Lagrange necessary conditions for control are simple to derive for this problem and have an almost linear behavior. Note the Hamiltonian is:

$$
\mathcal{H}(x, \gamma, \lambda) = F_0(x) + \gamma G_0(x) + \frac{r}{2} \gamma^2 + \lambda^T F(x) + \gamma \lambda^T G(x).
$$

The Hamiltonian is (strictly) convex in the control $\gamma$, and thus we propose the following:

**Lemma 6.** Any solution $\gamma^*$ to $\mathcal{H}_\gamma = 0$ satisfies the necessary conditions:

1. $\mathcal{H}_\gamma = 0$, and
2. $\mathcal{H}_{\gamma \gamma} > 0$, the strong Legendre-Clebsch condition;
therefore, it minimizes the Hamiltonian at all times.

Deriving the optimal control by solving $\partial H / \partial \gamma = 0$ for $u$ to obtain:

$$\gamma^* = -\frac{1}{r} \left( \lambda^T G(x) + G_0(x) \right).$$

(16)

The two conditions in Lemma 6, along with the fact that $x^*$ and $\lambda^*$ solve the resulting Euler-Lagrange two-point boundary value problem (see Expression 18), form the complete set of necessary conditions for the optimal control problem. Adding in the additional requirement that the corresponding matrix Riccati equation is bounded on $[0, t_f]$, these form sufficient conditions for a weak local minimal optimal controller [30, 31]. We discuss this sufficient condition in the sequel.

For simplicity, we refer to the optimal control as $\gamma$ (rather than $\gamma^*$) in the remainder of this paper and assume it is given by Equation 16. The adjoint dynamics are:

$$\dot{\lambda}^T = -(\nabla_x F_0(x))^T - \gamma (\nabla_x G_0(x))^T - \lambda^T D_x F - \gamma \lambda^T D_x G,$$

(17)

where $D_x F$ is the Jacobian (with respect to $x$). Thus we have the Euler-Lagrange two-point boundary value problem:

$$\begin{cases}
\dot{x} = F(x) + \gamma G(x), \\
\dot{\lambda} = -\nabla_x F_0(x) - \gamma \nabla_x G_0(x) - (D_x F)^T \lambda - u(D_x G)^T \lambda,
\end{cases}$$

(18)

$$x(0) = x_0, \quad \lambda(t_f) = \nabla_x \Psi(x[t_f]). \quad \text{(Transversality Condition)}$$

**Proposition 7.** If $u^*$ is an optimal control, then:

$$\gamma(t_f) = -\frac{1}{r} \left( \nabla_x \Psi(x(t_f))^T G(x(t_f)) + G_0(x(t_f)) \right).$$

(19)

**Proof.** This follows from the transversality condition. \qed

From Equation 16, note that:

$$r \dot{\gamma} = -\dot{\lambda}^T G(x) - \lambda^T (D_x G) \dot{x} - (\nabla_x G_0) \dot{x}.$$  

(20)

Then:

$$r \dot{\gamma} = (\nabla_x F_0(x))^T + \gamma (\nabla_x G_0(x))^T + \lambda^T (D_x F) + \gamma \lambda^T (D_x G) \right) G(x) - \lambda^T (D_x G) (F(x) + \gamma G(x)) - (\nabla_x G_0) (F(x) + \gamma G(x)).$$

(21)
Simplifying we have:

\[ r\dot{\gamma} = (\nabla_x F_0(x))^T G(x) - (\nabla_x G_0(x))^T F(x) + \lambda^T ((D_x F)G(x) - (D_x G)F(x)) . \]

If the Lie Bracket vanishes, i.e.,:

\[ [F, G] = (D_x F)G - (D_x G)F = 0, \tag{22} \]

then this simplifies to:

\[ \dot{\gamma} = \frac{1}{r} \left( (\nabla_x F_0(x))^T G(x) - (\nabla_x G_0(x))^T F(x) \right) , \tag{23} \]

and all co-state variables are eliminated. We have shown the following:

**Theorem 8.** Consider the general optimal control problem given in Expression 14. If \([F, G] = 0\) and \(\gamma\) is an optimal control, then the pair \((x(\gamma), \gamma)\) is a solution of the two point boundary value problem:

\[
\begin{aligned}
\dot{x} &= F(x) + \gamma G(x), \\
\dot{\gamma} &= \frac{1}{r} \left( (\nabla_x F_0(x))^T G(x) - (\nabla_x G_0(x))^T F(x) \right), \\
x(0) &= x_0, \\
\gamma(t_f) &= -\frac{1}{r} \left( (\nabla_x \Psi(x(t_f)))^T G(x(t_f)) + G_0(x(t_f)) \right).
\end{aligned}
\tag{24}
\]

Geometrically, Equation 22 implies that the flows derived by the vector fields \(F\) and \(G\) commute locally. From a game-theoretic view, this means that locally evolutionary motion caused by competition in uncontrolled game commutes with evolutionary motion caused by the actuation payoffs on local space/time scales. As we see in the sequel, this is not true for actuated cyclic games, but is true for quasi-linear approximations of the evolutionary dynamics as in [22].

It is worth noting that a differential equation for the control function is derived in [32], without the assumption of the vanishing Lie Bracket. However, without this assumption the system does not simplify in as useful a way and, in fact, in [32] the relevant Lie Bracket is not considered. Note, in formulating Theorem 8 we are assuming that solving the Euler-Lagrange equations will yield an optimal control. We can use the well known fact that
a sufficient condition for optimality is the boundedness of the solution to the matrix Ricatti equation [30, 31] to derive a complete necessary and sufficient condition for optimality of the control. Let:

\[ \dot{x} = F(x) + \gamma G(x) = f(x, \gamma). \]

Then the Matrix Ricatti equation is:

\[
\begin{cases}
-\dot{S} = D_{xx}H + (D_x f)^T S + S (D_x f) - \frac{1}{r} \left( D_{x} H + (\partial_{\gamma} f)^T S \right) \left( D_{x} H + (\partial_{\gamma} f)^T S \right), \\
S(t_f) = \nabla^2_x \Psi(x[t_f]).
\end{cases}
\] (25)

Here \( D_{xx} \) is the second differential operator with respect to the state and \( \partial_{\gamma} \) is an ordinary partial derivative, since there is only one control variable.

When taken together with Lemma 6, the system of differential equations in Theorem 8 and the co-state dynamics, Equation 17, we have a complete characterization of the necessary and sufficient conditions for the optimal control. This yields the corollary:

**Corollary 9** (Corollary to Theorem 8). Let \( f(x, \gamma) = F(x) + \gamma G(x) \) in the optimal control problem in Expression 14, with Hamiltonian \( H(x, \gamma, \lambda) \). Any solution to the system of differential equations:

\[
\begin{cases}
\dot{x} = f(x, \gamma), \\
\dot{\gamma} = \frac{1}{r} \left( (\nabla_x F_0(x))^T G(x) - (\nabla_x G_0(x))^T F(x) \right), \\
\dot{\lambda} = -\nabla_x F_0(x) - \gamma \nabla_x G_0(x) - (D_x F)^T \lambda - u(D_x G)^T \lambda, \\
-\dot{S} = D_{xx}H + (D_x f)^T S + S (D_x f) - \frac{1}{r} \left( D_{x} H + (\partial_{\gamma} f)^T S \right) \left( D_{x} H + (\partial_{\gamma} f)^T S \right), \\
x(0) = x_0, \\
\gamma(t_f) = -\frac{1}{r} \left( \nabla_x \Psi(x(t_f))^T G(x(t_f)) + G_0(x(t_f)) \right), \\
\lambda(t_f) = \nabla_x \Psi(x[t_f]), \\
S(t_f) = \nabla^2_x \Psi(x[t_f]),
\end{cases}
\] (26)

in which \( \gamma(t) = -\frac{1}{r} \left( \lambda^T G[x] + G_0[x] \right) \) and \( S \) is bounded for all \( t \in [0, t_f] \) constitutes a weak local optimal solution for Expression 14.
We note that this is the general analog of Proposition 2 in [28], which is specialized to a one-dimensional control problem. In general, checking the boundedness of the solution to the Matrix Ricatti equation must be done numerically. In the sequel we develop a simpler test for optimality using Mangasarian’s sufficiency condition; i.e., by checking that the Hamiltonian is jointly convex.

Problem \([C_N]\) does not satisfy the necessary condition that \([F, G] = 0\). However, a quasi-linearization of the problem does satisfy this condition (as in [22]). We now discuss a special case of Theorem \([S]\) as well as extensions that apply to this quasi-linearized form.

### 3.2. The Quasi-Linear Case

For the remainder of this section, let \(J\) and \(H\) be arbitrary matrices of appropriate size, rather than the Jacobian matrices derived in Lemmas \([3]\) and \([4]\).

In Problem \([14]\) let:

\[
\begin{align*}
F_0(x) &= \frac{1}{2}x^TQx, \\
G_0(x) &= 0, \\
F(x) &= Jx, \\
G(x) &= Hx.
\end{align*}
\]

(27)

where \(Q\) is a (symmetric) positive definite matrix of appropriate size. We will add additional criteria to \(J\) and \(H\) as we proceed. We refer to this as a quasi-linear case because the only non-linearity arises from the interaction of the state and control variables. The following Corollary is immediate from Theorem \([S]\).

**Corollary 10.** If \(JH = HJ\) and \(\gamma^*\) is an optimal control, then the pair \((x(\gamma^*), \gamma^*)\) is a solution of the two point boundary value problem:

\[
\begin{align*}
\dot{x} &= Jx + \gamma Hx, \\
\dot{\gamma} &= \frac{1}{r}x^TQHx, \\
x(0) &= x_0, \\
\gamma(t_f) &= -\frac{1}{r}x^T\nabla_x\Psi(x(t_f))Hx(t_f).
\end{align*}
\]

(28)
The condition that \( J \) and \( H \) commute is exactly the statement that the Lie Bracket of the vector fields in the dynamics vanishes. Therefore, Theorem 8 can be applied to any linear quadratic control problem where the state equation satisfies this condition.

We now derive some special results on \( \ddot{\gamma} \) and the optimal control in this quasi-linear case. Let \( K \triangleq QH \) and assume \( JH = HJ \). Computing the second derivative of \( \gamma \) yields:

\[
\dddot{\gamma} = \dot{x}^T K x + x^T \dot{K} \dot{x} = (x^T J^T + \gamma x^T H^T) K x + x^T K (J x + \gamma H x) = \\
x^T (J^T K + KJ + \gamma (H^T K + KH)) x.
\]

To simplify this, we will add an additional assumption to \( J \); suppose that \( J = -J^T \) (i.e., \( J \) is skew-symmetric) and \( JK = KJ \). Then:

\[
\dddot{\gamma} = x^T (H^T K + KH) x. \tag{29}
\]

Before proceeding note that:

\[
\frac{d}{dt}(x^T Q x) = (x^T J^T + \gamma x^T H^T) Q x + x^T Q (J x + \gamma H x) = \\
x^T (-JQ + QJ) x + \gamma x^T (H^T Q + QH) x = \\
x^T (-JQ + QJ) x + \gamma x^T (H^T Q + QH) x = \\
x^T (-JQ + QJ) x + 2\gamma x^T K x = \\
x^T (-JQ + QJ) x + 2r\gamma \dot{\gamma}.
\]

Thus, we have the following proposition and its corollary:

**Proposition 11.** If \( J = -J^T \), \( JH = HJ \) and \( JQ = QJ \) and \( K \triangleq QH \), then:

1. \( JK = KJ \),

2. \[
\frac{d}{dt}(x^T Q x) = 2r\gamma \dot{\gamma}, \tag{30}
\]

3. \[
\dddot{\gamma} = x^T (H^T K + KH) x. \tag{31}
\]
Corollary 12. For some constant $C$,

$$x^T Q x = r \gamma^2 + C$$  \hspace{1cm} (32)

is the implicit closed-loop control, where $C$ must satisfy:

$$C = x^T(t_f) Q x(t_f) - r \left( \frac{1}{r} \nabla_x \Psi(x(t_f)) x^T H x(t_f) \right)^2.$$ \hspace{1cm} (33)

Furthermore the optimal control $\gamma$ exists at time $t$ just in case:

$$x^T(t) Q x(t) - C \geq 0.$$ \hspace{1cm} (34)

4. Application to Complete Odd Circulant Games

We now return to the study of cyclic games with $N$ strategies and specifically to the control problem in Expression 13. As noted already, we cannot apply Theorem 8 directly to Problem 13 because the appropriate Lie Bracket does not vanish. However, we can construct the quasi-linearized form of the problem. Let $x = u - u^*$. The quasi-linearized problem is:

$$\tilde{\mathcal{C}}_N = \begin{cases} 
\min \int_0^{t_f} \frac{1}{2} \|x\|^2 + \frac{r}{2} \gamma^2 \; dt \\
\text{s.t.} \; \dot{x} = Jx + \gamma H x, \\
x(0) = x_0.
\end{cases} \hspace{1cm} (35)
$$

In Expression 35, $J$ and $H$ are the Jacobian matrices of $F(u)$ and $G(u)$ as defined in Lemmas 3 and 4. Problem 35 is an instance of the general control problem studied in Section 3.

The following useful fact follows at once from Lemma 3.

Corollary 13. The Jacobian matrix $J$ is skew-symmetric. \hfill \Box

Lemma 14. Let $\gamma$ be the optimal control for Problem 13. Then:

1. The (open-loop) optimal control obeys the following differential equations:

$$\dot{\gamma} = \frac{1}{r} x^T H x, \; \gamma(t_f) = 0,$$ \hspace{1cm} (36)

$$r \ddot{\gamma} = x^T (H^T H + HH) x.$$ \hspace{1cm} (37)
2. The following identity holds:

\[ x^T x = \|x\|^2 = r\gamma^2 + C, \]  

where:

\[ C = \|x(t_f)\|^2. \]

Proof. Problem 35 is an instance of Problem 14 but with quasi-linear system dynamics and quadratic objective as given in the quasi-linear conditions in Expression 27. In particular, Problem 35 sets \( Q = I_N \). As a consequence the matrix \( K = QH = H \). From Corollary 13 we know \( J \) is skew-symmetric. Further, since the circulant matrices form a commutative algebra, we have \( HJ = JH \). The lemma follows at once from Corollary 10, Proposition 11 and Corollary 12.

Expression 38 is the closed-loop control law for the controlled cyclic game. Furthermore, Equation 36 allows us to determine some structural properties of \( \gamma \).

Proposition 15. The matrix \( H \) is negative definite and therefore \( \dot{\gamma} \leq 0 \) for all \( t \).

Proof. Consider any vector \( x \in \mathbb{R}^N \). Then:

\[
x^T H x = \frac{1}{N^2} x^T (N(M_N - I_N) + I_N) x^T = \frac{1}{N^2} \left( N \left( \sum_{i=1}^{N} \sum_{j>i} x_i x_j - \sum_{i=1}^{N} x_i^2 - 2 \sum_{i=1}^{N} \sum_{j>i} x_i x_j \right) + \sum_{i=1}^{N} x_i^2 + 2 \sum_{i=1}^{N} \sum_{j>i} x_i x_j \right) = \frac{N-1}{N^2} \sum_{i=1}^{N} x_i^2 - \frac{N-2}{N^2} \sum_{i=1}^{N} \sum_{j>i} x_i x_j.
\]

Let \( S \in \mathbb{R}^{N \times N} \) be the upper-triangular matrix defined as:

\[
S_{ij} = \begin{cases} 
-\frac{N-1}{N^2} & \text{if } i = j, \\
-\frac{N-2}{N^2} & \text{otherwise.}
\end{cases}
\]

Then:

\[
x^T H x = x^T S x = -\frac{N-1}{N^2} \sum_{i=1}^{N} x_i^2 - \frac{N-2}{N^2} \sum_{i=1}^{N} \sum_{j>i} x_i x_j.
\]
The leading principal minors of $S$ alternate in sign (the diagonal is entirely negative) and thus by Sylvester’s criterion, $S$ is negative definite. It follows at once that $x^T H x < 0$ for all $x \neq 0$ and thus $H$ is negative definite. The fact that $\dot{\gamma} < 0$ now follows from Lemma 14.

Corollary 16. The optimal control $\gamma$ is a decreasing function on $[0, t_f]$.

In addition to determining that $\gamma$ is decreasing, Problem 35 has further special structure, which allows us to understand the structure of the derived control $\gamma$ in greater detail and ultimately derive a closed-form approximation for large $N$. The derivation is similar to the one found in [22] for a special case diffeomorphic to rock-paper-scissors.

Lemma 17. Let $H = D_u G(u)$. Then for all $x \in \mathbb{R}^N$:

$$x^T (H^T H + HH + H) x = -\frac{n}{N^2} \|x\|^2.$$  \hfill (39)

Proof. From Lemma 4 we have:

$$H = \frac{1}{N^2} \left( N (M_N - 1_N) + 1_N \right).$$

Let $R = M_N - 1_N$. The following computations are straight forward:

$$H^T H = \frac{1}{N^4} \left( N^2 R^T R + N R R^T 1_N + N 1_N^T R + 1_N^T 1_N \right),$$

$$H H = \frac{1}{N^4} \left( N^2 R R + N R 1_N + N 1_N R + 1_N 1_N \right).$$

Note that:

$$1_N^T 1_N = 1_N 1_N = N 1_N.$$  

We may also compute:

$$1_N M_N = 1_N^T M_N = n 1_N,$$

because $M_N$ contains $n$ unit entries in each column (row). Consequently:

$$(M_N^T 1_N)^T = 1_N^T M_N = n 1_N,$$

and therefore:

$$M_N^T 1_N = n 1_N^T = n 1_N.$$
Using this information, we compute:

\[ R^T 1_N = 1_N^T R = 1_N R = R 1_N = -(n + 1) 1_N. \]  \hspace{1cm} (40)

Thus:

\[
\begin{align*}
H^T H + H H + H &= \frac{1}{N^4} (N^2 (R^T + R) R - 4N(n + 1) 1_N + 2N 1_N) = \\
&= \frac{1}{N^4} (N^2 (R^T + R) R - 2N (2(n + 1) - 1) 1_N) = \\
&= \frac{1}{N^2} (N^2 (R^T + R) R - 2N^2 1_N) = \frac{1}{N^2} (\left( (R^T + R) R - 21_N \right)).
\end{align*}
\]

Using the fact that \( H = (NR + 1_N)/N^2 \), we may write:

\[
H^T H + H H + H = \frac{1}{N^2} \left( \left( (R^T + R + N 1_N) R - 1_N \right). \right.
\]

The circulant structure of \( M \) implies the identity:

\[ M^T + M = 1_N - I_N. \]

Therefore:

\[ R^T + R = 1_N - I_N - 21_N = -1_N - I_N. \]

Thus, using Equation \(40\) and the fact that \( N - 1 = 2n \):

\[
\begin{align*}
H^T H + H H + H &= \frac{1}{N^2} \left( ((N - 1)I_N - 1_N) R - 1_N \right) = \\
&= \frac{1}{N^2} \left( (N - 1)(M_N - 1_N) + (n + 1)1_N - 1_N \right) = \\
&= \frac{1}{N^2} (2nM_N - n1_N) = \frac{n}{N^2} (2M_N - 1_N).
\end{align*}
\]

Recall from Corollary \( 2\) that:

\[ x^T M_N x = \sum_{i=1}^{N} \sum_{j>i} x_i x_j. \]

Furthermore, it is straight forward to compute:

\[ x^T 1_N x = \sum_{i=1}^{N} x_i^2 + 2 \sum_{i=1}^{N} \sum_{j>i} x_i x_j. \]
Therefore:

\[ x^T (H^T H + HH + H) x = \frac{n}{N^2} x^T (2M_N - 1_N) x = \]
\[ \frac{n}{N^2} \left( 2 \sum_{i=1}^{N} \sum_{j>i} x_i x_j - \sum_{i=1}^{N} x_i^2 - 2 \sum_{i=1}^{N} \sum_{j>i} x_i x_j \right) = -\frac{n}{N^2} \|x\|^2. \]

This completes the proof. □

**Theorem 18.** If \( \gamma \) is the open-loop optimal control for Problem 35, then \( \gamma \) satisfies the following second order differential equation:

\[
\begin{cases}
  r\ddot{\gamma} + r\dot{\gamma} + \frac{n}{N^2} \gamma \left( r\gamma^2 + C \right) = 0, \\
  \gamma(t_f) = 0, \\
  \gamma'(0) = \frac{1}{r} x_0^T H x_0, \\
  C = \|x(t_f)\|^2.
\end{cases}
\] (41)

**Proof.** From Lemma 14 we have:

\[ r\ddot{\gamma} = x^T (H^T H + HH) x, \]

and

\[ r\dot{\gamma} = x^T H x. \]

Adding these together we obtain:

\[ r\ddot{\gamma} + r\dot{\gamma} = x^T (H^T H + HH + H) x. \]

Therefore by Lemma 17

\[ r\ddot{\gamma} + \dot{\gamma} = -\frac{n}{N^2} \|x(t)\|^2. \]

From Lemma 14 we have:

\[ r\ddot{\gamma} + \dot{\gamma} = -\frac{n}{N^2} (r\gamma^2 + C), \]

24
where \( C = \|x(t_f)\|^2 \). Thus:
\[
 r\ddot{\gamma} + \gamma \dot{\gamma} + \frac{n}{N^2} \gamma (r\gamma^2 + C) = 0.
\]

The boundary conditions \( \gamma(0) = 0 \) and \( \gamma'(0) = x_0^T H x_0 \) follows from Lemma 14.

**Corollary 19.** For \( N \) large, the open loop control \( \gamma \) can be approximated by \( \zeta \), a solution to the following two-point boundary value problem:

\[
\begin{aligned}
 r\ddot{\zeta} + r\zeta \dot{\zeta} &= 0, \\
 \zeta(t_f) &= 0, \\
 \zeta'(0) &= \frac{1}{r} x_0^T H x_0.
\end{aligned}
\]  

(42)

In practice, we will show that \( N \geq 5 \) is sufficient for this approximation to be valid.

### 4.1. Closed Form Analysis of the Limiting Behavior

For simplicity, let \( r = 1 \) in the following analysis. Corollary 19 can be made more useful by re-writing Equation 42 as a system of first order differential equations and examining the phase portrait (see Fig. 3):

\[
\begin{aligned}
 \dot{\zeta} &= v, \\
 \dot{v} &= -\zeta v, \\
 \zeta(t_f) &= 0, \\
 v(0) &= x_0^T H x_0.
\end{aligned}
\]  

(43)

The phase portrait indicates a sharp behavioral change in the direction field when moving from the \( v < 0 \) half-plane to the \( v > 0 \) half-plane. For the half-plane where \( v < 0 \), \( \gamma \geq 0 \) necessarily by Theorem 5. This is consistent with Proposition 15.

System 43 has a closed form solution\(^2\) with several branches. The relevant

\(^2\)Derived with Mathematica\textsuperscript{TM}.
Figure 3: The phase portrait of the first order system representing the limiting behavior of the open loop control $\gamma$ and its first derivative.
solutions on the interval \([0, t_f]\) are:

\[
\begin{align*}
\zeta(t) &= \sqrt{2} \sqrt{\kappa \tanh^2 \left( \frac{\sqrt{\kappa} (t_f - t)}{\sqrt{2}} \right)}, \\
\zeta'(t) &= -2\sqrt{\kappa} \sqrt{\kappa \tanh^2 \left( \frac{\sqrt{\kappa} (t_f - t)}{\sqrt{2}} \right)} \csc \left( \sqrt{2} \sqrt{\kappa} (t_f - t) \right).
\end{align*}
\]

Note, \(\zeta \sim O(|\tanh(\cdot)|)\). Thus, the usual behavior of \tanh is modified so that \(\zeta\) is a decreasing function on \([0, t_f]\) and then an increasing function outside this range. As a consequence, this solution is only valid on the control domain of interest.

In the closed form solution, \(\kappa\) is a constant of integration that must be chosen so that \(v(0) = \zeta'(0) = x_0^T H x_0\). Finding a closed form expression for \(\kappa\) is difficult. However as \(N\) increases, \(x_0^T H x_0\) decreases in size because \(H \sim 1/N\) and \(\|x\|\) is bounded, since \(x\) is just a translation of \(u \in \Delta_N\). For small values of \(x_0^T H x_0\), we expect \(\kappa\) to be small because of the structure of \(\zeta'(t)\). Furthermore, \(\zeta'(0)\) can be approximated as:

\[\gamma'(0) \approx -\kappa + O(\kappa^2).\]

Thus, setting \(\kappa = -x_0^T H x_0\) will give a reasonable approximation of the solution, as we illustrate in the examples below.

### 4.2. Sufficiency of the Euler-Lagrange Conditions

Corollary 9 contains both necessary and sufficient conditions for the computed \(\gamma(t)\) to be the optimal control. However, these conditions require the solution of the matrix Riccati equation. For the quasi-linearized optimal control problem on cyclic games, a simpler test can be constructed using Mangaserian’s condition, which states that the Hessian of the Hamiltonian must be positive definite (i.e., jointly convex in state and control). For the optimal control in quasi-linearized cyclic games, the Hamiltonian of this optimal control problem is:

\[
\mathcal{H}(x, \gamma, \lambda) = \|x\|^2 + \frac{1}{r} \gamma^2 + \lambda^T J x + \gamma \lambda^T H x.
\]

This is a specialization of Equation 15 to the quasi-linearized cyclic games problem. The Hessian of \(\mathcal{H}\) is:

\[
\mathcal{J} = \begin{bmatrix}
I_N & H^T \\
\lambda H & r
\end{bmatrix}.
\]
Theorem 20. If $r > \|H^T \lambda^T\|^2$ for all $t \in [0, t_f]$, then the control derived in Lemma 14 is optimal.

Proof. The Hessian matrix $\mathcal{H}$ is positive definite if and only if it has a Cholesky decomposition, which then implies that $\mathcal{H}(x, \gamma, \lambda)$ is convex in both its state and control. Computing the Cholesky decomposition for $\mathcal{H}$ we obtain:

$$
\mathcal{H} = \begin{bmatrix}
I_N & 0 \\
\lambda^T H & \sqrt{r - \|H^T \lambda^T\|^2}
\end{bmatrix}
\begin{bmatrix}
I_N & H^T \lambda^T \\
0 & \sqrt{r - \|H^T \lambda^T\|^2}
\end{bmatrix}.
$$

This decomposition exists if and only if $r > \|H^T \lambda^T\|^2$. The result follows immediately.

As we demonstrate in the examples, this sufficient condition for optimality is precisely the one identified in [22] for the triple public goods game, which was shown to be diffeomorphic to the cyclic game with three strategies (rock-paper-scissors).

4.3. Examples with $N = 3, 5, 7, 9$

We study the derived optimal controls for the case when $N = 3, 5, 7, 9$ in both the fully non-linear optimal control problem and the quasi-linearized optimal control problem. In particular we observe similar structure to the optimal controls in all cases. For these examples, we set $t_f = 6$, except in the last case where we extend it to show an example where the sufficient condition for optimality is not satisfied.

In Figure 4 we show the optimal control for both the non-linear and quasi-linearized optimal control problems. We set $r = 0.2$ and the initial state $u_0 = (0.2333, 0.3333, 0.43333)$, which is close enough to the fixed point for the quasi-linearized approximation to be valid. We also demonstrate the equivalence between the solution to the quasi-linearized Euler-Lagrange equations and the second order differential equation (Eq. 41). We also show the approximation to the quasi-linearized control function that arises as a solution to Equation 42. In the 3 strategy case, the condition for optimality is:

$$
r > \|H^T \lambda^T\|^2 = \frac{1}{9} \|\lambda\|^2.
$$

(44)
This is not generally true, but it is equivalent to the sufficient condition derived in [22] for the diffeomorphic triple public goods game. Thus, Theorem 20 generalizes the results from [22].

In Figure 5 we show the relevant control plots for the 5 strategy cyclic game (rock-paper-scissors-Spock-lizard). We again use \( r = 0.2 \) and set \( \mathbf{u}_0 = (0.1, 0.3, 0.1, 0.3) \). An interesting feature of the 5 strategy cyclic game is that the limiting approximation (Equation 42) does not perform as well as it did for the 3 strategy game. As we see in Figures 6 and 7, the approximation does improve (as we expect) as \( N \) increases. This anomalous behavior may be a function of numerical instability or a property of the 5 strategy cyclic game. We do note that because of the properties of Equations 41 and 42 (i.e., branching solutions), we did observe some numerical instability when simulating these systems. We note that in the 5 strategy case, the sufficient condition on optimality is satisfied.

In Figures 6 and 7 we illustrate the optimal control for 7 and 9 strategy games. In these cases \( r = 0.2 \) again. To maintain feasibility of the starting solution, we set \( \mathbf{u}_0 \) by alternately adding and subtracting 0.05 from the equilibrium, but kept the third strategy at proportion \( 1/N \) in both cases. Thus

---

\(^3\)Developed by Sam Kass. See [http://www.samkass.com/theories/RPSSL.html](http://www.samkass.com/theories/RPSSL.html) or Episode 8, Season 2 of *The Big Bang Theory*. Note, to properly organize the moves to produce a circulant matrix, the strategies should be ordered as rock-paper-scissors-Spock-lizard rather than rock-paper-scissors-lizard-Spock as they are on *The Big Bang Theory*. Kass correctly organizes the strategies.
we assured \(u_0\) was in \(\Delta_N\) in both cases. As we expect, as \(N\) increases, the approximation in Equation 42 improves. It is also interesting to note that the general structure of the optimal control function is similar in all cases with the quasi-linearized control. It exhibits almost linear behavior, and the fully non-linear controller shows decreasing oscillation. That the optimal controller is a decreasing function is consistent with Proposition 15.

We can analyze the control problem even when the starting state is not near the fixed point, which yields a case where the sufficient condition for optimality fails to hold. We again consider the case when \(N = 3\) and extend the time horizon of control to \(t_f = 15\). We start at the point \(u_0 = (0.8, 0.1, 0.1)\),
which is not near the equilibrium point $u^* = \frac{1}{3} 1$, thus reducing the accuracy of the quasi-linearized approximation. The objective of this example is to study both the extended time control horizon as well as the control that results when the starting point is further from the equilibrium point.

We compute an optimal control using the fully non-linear Euler-Lagrange equations, the Euler-Lagrange equations for the quasi-linearized system, and the exact differential equation for $\gamma$ given in Lemma 14. As demonstrated in Figure 8, the quasi-linearized control functions are identical to each other (as expected), and they are highly correlated to the control function for the fully non-linear system. The co-state, however does not satisfy the sufficient condition $r > H^T \lambda$. Here $r = 0.2$, as in the previous examples. We can still analyze this problem by solving the matrix Riccati equation as given in Theorem 8 to show that it is bounded, and thus the control identified for the quasi-linearized system is optimal. The matrix Riccati equation for this system is:

$$-\dot{S} = I_3 + (J + \gamma H)^T S + S (J + \gamma H) - \frac{1}{r} \left( \lambda^T H + x^T H^T S \right)^T \left( \lambda^T H + x^T H^T S \right),$$

$$S(t_f) = 0.$$ 

This system of equations contains nine equations because $S$ is $3 \times 3$. As shown in Figure 8, the solution curves for this equation are all bounded on the time interval of consideration. Furthermore, since the state and co-state necessarily satisfy the Euler-Lagrange equations, and the Hamiltonian
Figure 8: A solution that violates the sufficient condition for optimality $r > H^T \lambda$ but can be shown to be optimal by appealing to the matrix Riccati equation, which has bounded solutions for $t \in [0, t_f]$. We compare the solution to the ordinary controller derived from the ordinary Euler-Lagrange equations and the controller that is directly computed using Lemma 14. Note they are identical as expected.
is convex in $\gamma$ and $\gamma$ (and therefore maximizes the Hamiltonian at all times (seeLemma 6), the control function must be (locally) optimal.

Note that while the starting point in this example is not near the equilibrium point, the control computed for the quasi-linear approximation is still highly correlated to the control computed for the non-linear system. Thus, in this case quasi-linearization still provides a reasonable approximation to the optimal control in the non-linear system.

5. Final Discussion and Future Directions

In this paper we studied an optimal control problem arising from the class of complete, odd circulant games that generalize rock-paper-scissors. We used the replicator dynamics as the natural equations of motion in the optimal control problem. In particular, the control problem was to drive trajectories toward the unique interior fixed point of the replicator dynamics. We first studied the uncontrolled fixed points of the replicator. We then showed that this class of problems admits a natural quasi-linearization, and that this quasi-linearized optimal control problem has a open-loop optimal control satisfying a specific second order differential equation. Furthermore, we showed that as the number of strategies grows, this differential equation admits a closed form solution. Numerical comparisons showed that this limiting case provides a natural approximation for the optimal control. We also showed that even when the starting conditions for the optimal control are far from the interior Nash equilibrium, where quasi-linearization is performed, we still can use it to approximate the optimal control in the original problem.

Unfortunately, the results presented in this paper do not apply to arbitrary circulant games or to cyclic games with a control parameter. In this context, a cyclic game is any circulant game in which the first row of the $L_N$ matrix has form $(0, 1, 0, \ldots, 0, -1)$. Here the number of 0’s between 1 and $-1$ is $N - 3$. The resulting matrix $M_N$ with 1’s corresponding to the 1’ in $L$ and 0 elsewhere is the adjacency matrix of a cycle graph. Rock-paper-scissors is the only game that is both a cyclic and complete odd circulant graph (because the three-cycle is the complete graph on three vertices). Any circulant game whose payoff matrix can be written as $L_N + \gamma M_N$ will obey Equation 36 because the circulant matrices form a commutative algebra. Beyond that, it is possible addition dynamics govern the optimal controls in these cases. This presents a logical area for further study.
Another logical extension of this work is to study circulant games with an off-center interior equilibrium point, rather than $u^* = \frac{1}{N} 1$. Doing so, however, should introduce additional control parameters. This would be an interesting extension as well since this paper considered only a single control parameter. It also will make the application more realistic since an individual may have varying degrees of control over each population. In addition to introducing additional controls, another natural extension of this work is to derive controllers that drive the system toward a non-interior equilibrium point. In particular it would be intriguing to study the problem of deliberately eliminating one or more species.

Finally, studying more complex dynamics with control, like the mutator-replicator, may produce interesting and useful results. However, these may not admit the necessary conditions to allow the control mechanisms identified in this paper to be applied.

**Appendix A. Optimal Control Problems**

In Section 3 we introduce the problem of driving a population playing a cyclic game to its mixed strategy equilibrium. We present key facts from optimal control theory used in this study. Details are available in [33, 34, 35].

A Bolza type optimal control problem is an optimization problem of the form:

$$\begin{align*}
\min \ & \Psi(x(t_f)) + \int_{t_0}^{t_f} f(x(t), u(t), t) dt \\
\text{s.t.} \ & \dot{x} = g(x(t), u(t), t), \\
& x(0) = x_0.
\end{align*}$$

(A.1)

When $\Psi(x(t_f)) \equiv 0$, this is called a Lagrange type optimal control problem. The vector of variables $x$ is called the state, while the vector of decision variables $u$ is called the control. Additional constraints on $u$, $x$ or the joint function of $x$ and $u$ can be added.
The Hamiltonian with adjoint variables (Lagrange multipliers) $\lambda$ for this problem is:

$$H(x, \lambda, u) = f(x(t), u(t), t) + \lambda^T g(x(t), u(t), t).$$

In what follows, we assume that all $f(x, u, t)$ and $g(x, u, t)$ are continuous and differentiable in $x$ and $u$, and $\Psi(x(t_f))$ is continuous and differentiable in $x(t_f)$. A proof of this lemma can be found in almost every book on optimal control (e.g. \cite{35}).

**Lemma 21** (Necessary Conditions of Optimal Control). If $u^*$ is a solution to Optimal Control Problem (A.1), then there is a vector of adjoint variables $\lambda^*$ so that:

$$H(x^*(t), u^*(t), \lambda^*(t)) \leq H(x^*(t), u(t), \lambda(t)) \quad (A.2)$$

for all $t \in [0, T]$ and for all admissible inputs $u$, and the following conditions hold:

1. Pontryagin’s Minimum Principle: $\dot{u}(t) = \frac{\partial H}{\partial u} = 0$ and $\frac{\partial^2 H}{\partial u^2}$ is positive definite,

2. Co-State Dynamics:

$$\dot{\lambda}(t) = -\frac{\partial H}{\partial x} = -\lambda^T(t) \frac{\partial g(x, u)}{\partial x} + \frac{\partial f(x, u)}{\partial x},$$

3. State Dynamics: $\dot{x}(t) = \frac{\partial H}{\partial \lambda} = g(x, u),$

4. Initial Condition: $x(0) = x_0$, and

5. Transversality Condition: $\lambda(t_f) = \frac{\partial \Psi}{\partial x}(x(t_f)).$

We will use the following restricted form of Mangasarian’s Sufficiency condition \cite{33} to argue a controller we derive in Section \ref{section:controllers} is the optimal controller.

**Lemma 22** (Mangasarian’s Sufficiency Condition - Restricted Form). Suppose $(x^*, u^*)$ satisfies the necessary conditions from Lemma 21 and $H$ is jointly convex in $x$ and $u$ for all time, and $\Psi(x(t_f)) \equiv 0$. Then $(x^*, u^*)$ is a globally optimal control in the sense that it minimizes the objective functional.

We note that Mangasarian’s Sufficiency Condition specifically implies the strong Legendre-Clebsch necessary conditions for optimality of the control:
1. $\mathcal{H}_\alpha = 0$, and
2. $\mathcal{H}_{uu} < 0$.

In the paper, we also discuss the sufficiency of the boundedness of the matrix Riccati equation. Since this plays only a small role in our overall analysis, we introduce this when it is needed.
