e-mail: wjacek@fuw.edu.pl

Abstract

Lieb and Schupp have obtained, using certain version of “spin-reflection positivity” method, a number of ground-state properties for frustrated Heisenberg models. One group of these results is related to singlet nature of ground state and it needs an assumption of reflection symmetry present in the system. In this paper, it is shown that the result holds also for other symmetries (inversion etc.). The second Lieb-Schupp result is relation between ground-state energies of certain systems. In the paper, this relation is applied to multidimensional models on various lattices.

FIG. 1: Example of frustrated spin system.

I. INTRODUCTION

Geometric frustration takes place, when no arrangement of spins on the lattice is possible in such a way that all interactions minimize their energy (see FIG. 1). The canonical example is an antiferromagnetic Ising model on triangular lattice [1]. Another systems where the geometric frustration is particularly strong, are antiferromagnetic systems on kagomé, pyrochlore, or (in d=3) fcc cubic lattices.

Frustrated systems are both very interesting and hard to analyse and understand, both in classical version and especially in the quantum case. The source of these difficulties traces back to the large ground-state degeneracy in the classical version. Such systems are very sensitive to perturbations. A consequence is possibility of very complicated phase diagram at finite temperatures. This situation takes place, for instance, in an ANNNI model [3] (infinite number of phases, devil’s staircase, etc). Besides of numerous efforts and important results, [2], [3], [4], (for reviews, see [5], [6], [8]), full treatment of such systems is not worked out so far.

The situation for quantum frustrated antiferromagnets is even less clear. It is generally suspected that the ground state emerging as a linear combination of many classical configurations is a featureless, “spin liquid” state, i.e. state without long-range ordering, where correlation functions fall-off exponentially. However, one cannot exclude another scenario: “order by disorder” – exotic orderings absent in a classical version of these models. Such scenarios are moreover sensitive to the underlying lattice structure. (For a review, see for instance [7]). To my best knowledge, no general definite conclusions have been obtained here.

Most informations obtained comes from analysis using approximate methods, such as guessing of ground-state wave functions, numerical diagonalization of small systems, spin
waves, semiclassical (i.e. large-S) approximations. However, it is difficult to estimate how reliable are these approximations. For this reason, exact results are very desirable. However, they are very exceptional.

In such a situation, exact results obtained by Lieb and Schupp [9], [10] (summarized also in [11]) for fully frustrate systems are of first importance. They are interesting both as themselves and moreover, they can serve as a test of validity of approximate methods. Results obtained in [9], [10] can be divided into two groups. The first one concern ground-state properties for such systems and it can be summarized as follows: ground states are singlets; zero-field magnetization is zero; susceptibility is bounded by certain constant. One of assumptions of these theorems is reflection symmetry. It was apparent that this method could work also for another kind of symmetry, not necessarily reflection one. Such a generalization turned out to be possible, and this is the first result of the paper.

The second collection of results [10] concern comparison of ground state energies for spin rings. It turned out that similar results hold for more complicated systems (multidimensional lattices). This is second result of the paper.

The outlook of the paper is as follows. In Sec. II the basic ingredients of Lieb and Schupp technique is presented. Some systems not mentioned in [9], [10], for which they results hold, are listed. Then modifications of their technique to systems exhibiting symmetry other than reflection one (rotation or inversion) are described. In Sec. III Lieb and Schupp results concerning comparison of ground-state energies for spin rings with the use of certain matrix inequality are described. Then it is discussed how this technique can be applied to other systems – for instance g.s. energies of systems on different lattices. Section Sec. IV contains short summary and conclusions. The Appendix contains proof of Lieb-Schupp inequality, which is fundamental for Sec. III.

II. LIEB-SCHUPP APPROACH AND GENERALIZATIONS FOR SPIN SYSTEMS WITH SYMMETRIES

A. Reflection-symmetric systems

1. Assumptions

We make the following assumptions concerning systems under consideration.
1. We consider Heisenberg models for arbitrary spin. (Below we consider mainly the $s = 1/2$ case, but generalization to other spin values is straightforward).

2. The system is invariant with respect to the reflection about the $O$ axis ($d-1$ plane for $d$-dimensional system). The system consist of two parts ("Left" and "Right" ones), which are interchanged under reflection (see FIG. 2). The Hamiltonian is a sum of three parts: $H_L$, $H_R$ and $H_C$; $H_L$ acts only on the left part (i.e. $H_L = h \otimes 1$), whereas $H_R$ acts on the right one (i.e. $H_R = 1 \otimes h$). $H_C$ is the Hamiltonian for "crossing bonds" (i.e. for bonds which intersect the symmetry line). It has the form:

$$H_C = \sum_{i \in L, i' \in R} j_{i,i'} s_i \cdot s_{i'}$$

where $j_{i,i'}$ is a diagonal matrix with non-negative diagonal elements. $s_i$ can have various nature; it can be a single spin or, more generally, it can have the form: $s_i = \sum_{\alpha \in L} j_{i;\alpha} s_{\alpha}$, where $j_{i;\alpha}$ are real coefficients. The objects $s_i$ can be different for different indices $i$. Under reflection operation, $H_L$ is transformed to $H_R$ and vice versa, whereas $H_C$ transforms into itself.

3. $H_L$ and $H_R$ are (almost) arbitrary: the only limitations are: both commute with the total spin operator, and

4. moreover, operators are real in the $S^3$ basis.
2. **Ground state properties**

Every state of the system can be expressed as a linear combination:

\[
\psi = \sum_{\alpha, \beta} c_{\alpha \beta} \psi^L_{\alpha} \otimes (\psi^R_{\beta})_{\text{rot}},
\]

where states \(\psi^L_{\alpha}\) form a real orthonormal base of \(S^3\) eigenstates for the left subsystem, whereas \((\psi^R_{\beta})_{\text{rot}}\) are corresponding *rotated* states for the right subsystem. (The rotation – meant as an operation in the spin space – acting for the state: \(|s, m\rangle\) produces the state \((-1)^{s-m}|s, -m\rangle\)).

The eigenvalue problem: \(H \psi = E \psi\) can be written as a matrix equation for \(c\) matrix:

\[
h_L c + c(h_R)^T - \sum_{i=1}^{3} \sum_y t^{(i)}_y c(t^{(i)}_y)^T = Ec,
\]

where \((h_L)_{\alpha\beta}\) and \((h_R)_{\alpha\beta}\) are real, symmetric matrices for corresponding terms of the Hamiltonian, whereas \(t^{(i)}_y\) are real matrices, defined for spin operator \(s_y = \sum_{\alpha \in L} j_{y;\alpha} s_{\alpha}\) (in the \(y\)-th "bond") by: \(t^{(1,3)}_y = \langle \psi^L_{\alpha}|s^{(1,3)}_y|\psi^L_{\beta}\rangle\) and \(t^{(2)}_y = i \langle \psi^L_{\alpha}|s^{(2)}_y|\psi^L_{\beta}\rangle\). Notice the total "minus" sign before third term in (3); it is so because replacement of \(s_y\) by \(s_y'\) gives sign change for components 1 and 3, whereas the \(i\) factor in definition of \(t^{(2)}\) gives minus sign for component 2.

The energy expectation value, expressed in term of the \(c\) matrix, is

\[
\langle \psi|H|\psi\rangle = \text{Tr}(cc^\dagger h_L) + \text{Tr}(c^\dagger h_Rc) - \sum_{y,i} \text{Tr} c^\dagger t^{(i)}_y c(t^{(i)}_y)^\dagger.
\]

Lieb and Schupp have established a number of results concerning ground states of reflection-symmetric systems. There are:

1. The \(c\) matrix is hermitian, i.e. without loss of generality we can express eigenstates of \(H\) by *hermitian* matrix \(c = c^\dagger\). (It is proved using the left-right symmetry and a form (4) for energy).

2. Let the \(c\) matrix corresponds to the ground state; then, also the \(|c|\) matrix corresponds to the ground state. Here \(|c| = \sqrt{c^2};\) we take the unique positive square root. (It is proved by writing down (4) in the diagonal basis).

3. This implies that we can choose the base for ground states as a collection of functions built up from positive semi-definite (p.s.d.) coefficient matrices.
4. The overlap of the ground state with canonical spin-zero state (given by unit matrix in a basis of $S^{(3)}$ eigenstates in either subsystem) is non-zero.

5. It implies that there exist ground state with spin zero, and moreover, that coefficient matrix for this state is positive semidefinite. It follows from the inequality: $E_b \geq E_0$ ($E_b$ is an energy of the system in the magnetic field $b$), which in turn is proved using the matrix inequality (5).

6. We have "ice rule" for frustrated units, i.e. for collection of spins appearing in the expression $s_i \cdot s_i'$. More precisely, if we denote: $s_i = \sum_{\alpha \in L} j_{\alpha} s_\alpha$, then the expectation of the third component of sites in each crossing bond vanishes for any ground state $|\psi_0\rangle$:

$$\langle \psi_0 | s_i + s_i' | \psi_0 \rangle$$

Under additional assumptions, these results can be made stronger. For instance, if the system has periodic boundary condition in at least one direction, then all ground states are singlets. Moreover, the magnetic susceptibility is bounded from above, both in the ground state and in positive temperatures.

**Remark.** Lieb and Schupp in [9] and [10] have developed general method and (almost) haven’t given examples of systems where their method could apply; the only example discussed is the checkerboard pyrochlore lattice. Some further examples of physical interest, where their results are applicable, are:

- $J_1 - J_2$ 2d Heisenberg model:

$$H = J_1 \sum_{n.n.} s_i \cdot s_j + J_2 \sum_{n.n.n.} s_i \cdot s_j$$

considered by numerous authors (see, for instance, [12] and references therein). This model is very interesting, as when $J_2/J_1$ is varied, it exhibits a transition from ordered, antiferromagnetic state to the 'glassy', non-magnetic, spin-liquid-like one. Lieb and Schupp results apply for $J_2 \leq \frac{1}{2} J_1$. Most of approximate methods assume that ground state is singlet. Lieb and Schupp results can be used to justify this assumption. Moreover, it can serve also as a test of these methods by supplying rigorous upper bounds for susceptibility.
• Axial Next-Nearest-Neighbour Heisenberg (ANNNH) model \[5\]. This is Heisenberg model with two coupling constants; we have isotropic coupling \(J_1\) between nearest neighbours, and moreover, there is coupling \(J_2\) between second neighbours along one of the axes (say, \(z\) axis). Such models have been used to describe helical and incommensurate configurations, and Lifshitz points in magnets (\[5\] and references therein). Lieb-Schupp results can be applied when both constants are antiferromagnetic, or when \(J_1\) is AF and \(J_2\) is F (in this case, one should take the reflection plane to be parallel to the line formed by \(J_2\) couplings).

B. Generalization to other symmetries

In the course of proofs in the previous Subsection, geometric properties of systems exhibiting reflection symmetry were not employed. Only assumption which was used was that \(h_L\) transforms into \(h_R\) and vice versa; particular nature of this transformation was not essential. It suggests that more general symmetry operations than reflection are allowed. It is the case; more precise formulation is as follows.

We make assumptions identical as 1., 3. and 4. in Subsec. II A 1; the assumption 2. is changed into the following one.

2’. The system again can be divided by two identical parts "L" and "R", each of them is described by the Hamiltonians \(H_L = h \otimes 1\) and \(H_L = 1 \otimes h\), respectively. \(H_C\) is the Hamiltonian for "bonds" between spins in \(L\) and \(R\) subsystems. It has the form:

\[
H_C = \sum_{i \in L, i' \in R} \gamma_{i,i'} s_i \cdot s_{i'}
\]

where the symmetric \(\gamma_{i,i'}\) matrix is positive definite. One can view on this property as a demand that \(H_C\) has to be “globally antiferromagnetic”, i.e. some coupling constants \(\gamma_{i,i'}\) can be negative (ferromagnetic), however, the whole matrix \(\gamma\) has to be positive definite.

The whole system is invariant with respect to the some symmetry operation \(T\), such that \(T^2 = \text{Id}\); \(T\) transforms the "L" subsystem into "R" one and vice versa. The following operations: reflection, \(C_2\) rotation (see FIG. 3), or inversion can serve as examples of such operation. Under action of \(T\), \(H_L\) transforms into \(H_R\), \(H_R\) into \(H_L\) and \(H_C\) into itself.

The system described above can be easily transformed into form equivalent to the one considered in the previous Subsection. Let us notice that \(H_C\) is \textit{bilinear} in \(s_i, s_{i'}\). Then, the
FIG. 3: System exhibiting inversion symmetry.

form: \( H_G = \sum_{i \in L, i' \in R} \gamma_{i,i'} s_i \cdot s_{i'} \) can be diagonalized by suitable linear transformation in the spin variables on "L" and the same transformation on "R". After diagonalization, \( H_G \) takes the form

\[
H_G = \sum_{I \in L, I' \in R} J_{I,I'} \sigma_I \cdot \sigma_{I'}
\]

where the matrix \( J_{I,I'} \) is diagonal and has only non-negative elements. Then, we have system in the form analogous as (1) and one can repeat all considerations from previous Subsection, obtaining analogous results. One should only remember that the "ice rule" concern spin variables after diagonalizing transformation, i.e. we have

\[
\langle \psi_0 | \sigma_I + \sigma_{I'} | \psi_0 \rangle = 0.
\]

III. TRACE INEQUALITY AND COMPARISON OF GROUND-STATE ENERGIES FOR VARIOUS SYSTEMS

Lieb and Schupp have proved beautiful inequality for traces of matrices. It is crucial in further considerations.

**Theorem** ([10], [11]). For any square matrices \( c, M, N \) it is true that

\[
|\text{Tr} c^\dagger M c N^\dagger| \leq \frac{1}{2} (\text{Tr} c_L M c_L M^\dagger + \text{Tr} c_R N c_R N^\dagger),
\]

(5)

where \( c_R = \sqrt{c^\dagger c}, \ c_L = \sqrt{c c^\dagger} \) are unique (positive) square roots from positive definite matrices \( c^\dagger c \) and \( c c^\dagger \).
For the convenience of reader, the proof is supplied in the Appendix. Now let us notice that the inequality \(5\) still remains valid if matrices \(c, M, N\) are rectangular ones: If \(c\) is \(m \times n\) matrix, then \(M\) is \(m \times m\) matrix, \(N\) is \(n \times n\) matrix, \(u\) is partial isometry, whereas \(c_L\) and \(c_R\) are positive matrices of dimension \(m \times m\) and \(n \times n\), respectively.

Now, let us consider the system without reflection symmetry, which however still consists of the ”left” subsystem \(L\) described by \(H_L\) and the ”right” subsystem \(R\) described by \(H_R\). The full system will be denoted by \(L−R\), and its Hamiltonian \(H_{L−R}\) contains also the ”crossing bond” term \(H_C\), describing ”interaction” of these two parts: \(H_{L−R} = H_L + H_R + H_C\). Every state of the system can be written in the form \(2\). We change slightly the notation and write an analogon of \(2\) as:

\[
\psi = \sum_{\alpha, \beta'} c_{\alpha\beta'} \psi^{L}_{\alpha} \otimes (\psi^{R}_{\beta'})_{\text{rot}},
\]

(6)

to distinguish between indices referring to the \(L\) part (unprimed) and \(R\) (primed ones). Remember that the \(c\) matrix is now, in general, the rectangular one.

Consider first the situation, where \(H_C\) contains only one bond:

\[
H_C = s \cdot S,
\]

where \(s\) belongs to \(L\) and \(S\) belongs to \(R\). One can write expression for the mean value of energy in the manner analogous as Eq. \(4\):

\[
E_{L−R} = \text{Tr} \; c c^\dagger h_L + \text{Tr} \; c^\dagger c h_R - \frac{1}{2} \sum_{\mu=1}^{3} \text{Tr} \; [c^\dagger t^{(\mu)} c (T^{(\mu)})^\dagger],
\]

(7)

where: \(h_L, h_R\) are matrices of corresponding hamiltonians. \(t\) refers to the left subsystem, whereas \(T\) to the right one; \(t, T\) matrices are given by: \(t^{(1,3)}_{\alpha\beta} = \langle \psi_{\alpha}^{L} | s^{(1,3)} | \psi_{\beta}^{L} \rangle\), \(t^{(2)}_{\alpha\beta} = i \langle \psi_{\alpha}^{L} | s^{(2)} | \psi_{\beta}^{L} \rangle\), and similarly for \(T\): \(T^{(1,3)}_{\alpha'\beta'} = \langle \psi_{\alpha'}^{R} | S^{(1,3)} | \psi_{\beta'}^{R} \rangle\), \(T^{(2)}_{\alpha'\beta'} = i \langle \psi_{\alpha'}^{R} | S^{(2)} | \psi_{\beta'}^{R} \rangle\).

Inequality \(5\) applied to the last term of \(7\) gives:

\[
- \frac{3}{2} \sum_{\mu=1}^{3} \text{Tr} \; c^\dagger t^{(\mu)} c (T^{(\mu)})^\dagger \geq \frac{1}{2} \sum_{\mu=1}^{3} (\text{Tr} \; c_L t^{(\mu)} c_L (t^{(\mu)})^\dagger + \text{Tr} \; c_R T^{(\mu)} c_R (T^{(\mu)})^\dagger)
\]

Then, we can write:

\[
E_{L−R} \geq \text{Tr} \; c c^\dagger h_L + \text{Tr} \; c^\dagger c h_R - \frac{1}{2} \sum_{\mu=1}^{3} (\text{Tr} \; c_L t^{(\mu)} c_L (t^{(\mu)})^\dagger + \text{Tr} \; c_R T^{(\mu)} c_R (T^{(\mu)})^\dagger)
\]

9
\[
\begin{align*}
&= \text{Tr} \, c_L c_L h_L + \text{Tr} \, c_R c_R h_R - \frac{1}{2} \sum_{\mu=1}^{3} (\text{Tr} \, c_L t^{(\mu)} c_L (t^{(\mu)})^\dagger + \text{Tr} \, c_R T^{(\mu)} c_R (T^{(\mu)})^\dagger) \\
&= \frac{1}{2} (\text{Tr} \, c_L^\dagger c_L h_L + \text{Tr} \, c_R^\dagger c_R h_R - \sum_{\mu=1}^{3} \text{Tr} \, c_L^\dagger t^{(\mu)} c_L (t^{(\mu)})^\dagger) \\
&\quad + \frac{1}{2} (\text{Tr} \, c_R^\dagger c_R h_R + \text{Tr} \, c_R^\dagger c_R h_R - \sum_{\mu=1}^{3} \text{Tr} \, c_R^\dagger T^{(\mu)} c_R (T^{(\mu)})^\dagger).
\end{align*}
\]

How can we interpret two last expressions? They resemble very much ground-state energies for the following systems: the first one consists of two copies of $L$ subsystem with ”interaction” Hamiltonian \[H_C = s \cdot s',\] where $s$ belongs to $L$, whereas $s'$ to its twin copy (let’s denote it as the $L - L$ system). The second one consists of two copies of $R$ subsystem with \[H_C = S \cdot S',\] (it will be denoted as $R - R$ system). More precisely, they are energies of trial functions, built up from matrices $c_L$ and $c_R$, respectively. From variational principle, they are greater than true ground-state energies, so we have the general inequality for ground-state energies for three systems $L - R, L - L, R - R$:

\begin{equation}
2E_{L-R} \geq E_{L-L} + E_{R-R}.
\end{equation}

Considerations above concerned the situation, where ”interaction” part was the only ”bond” \[s \cdot S.\] Generalization to multi-bond case is immediate. Let’s have general ”interaction” hamiltonian:

\[H_C = \sum_{i \in L} \sum_{j' \in R} J_{ij'} s_i \cdot s_{j'};\]

where we assume that \[J_{ij'}\] are positive numbers. Then, the inequality (10) is still true for systems $L - L$ and $R - R$ with ”interaction” hamiltonians: \[H_C = \sum_{i \in L} \left( \sum_{j' \in R} J_{ij'} \right) s_i \cdot s_{i'}\] for the $L - L$ system, and \[H_C = \sum_{j' \in R} \left( \sum_{i \in L} J_{ij'} \right) s_{j'} \cdot s_{j'}'\] for $R - R$ system.

Lieb and Schupp have applied inequality (10) to spin rings, getting the following relation between ground-state energies $E_k$ for rings with $k$ spins:

\[2E_{n+m} \geq E_{2n} + E_{2m}\]

However, it seems that it can be used in much more general situations, if we consider the multi-bond case.

Examples.
1. For spin chains (Fig. 4.), we have analogous inequality:

$$2E_{n+m} \geq E_{2n} + E_{2m}.$$  \hspace{1cm} (11) 

2. Rather obvious is generalization of this result for systems defined on subsets of $\mathbb{Z}^d$ for $d > 1$ (rectangles, parallelepipeds etc) ($d = 2$ case is illustrated on Fig. 5); as a result, we again have inequality (11), where $m, n$ are lengths of systems in direction perpendicular to reflection line (plane for $d = 3$).

3. Consider system defined on a rectangular subset of square lattice (see Fig. 6). Divide it into $L$ and $R$ part in nonsymmetric manner (in this example, this division is realized by the “snaky” line). Then, we obtain the inequality (11) for systems as pictured on Fig. 6.

4. Consider “zig-zag ladder” (see Fig. 7). Divide it into parts $L$ and $R$ by the line going
FIG. 6: Division of the system defined on a rectangular subset of square lattice into $L$ and $R$ subsets by “snaky” line. Single lines denote coupling constants equal to $J$, double lines correspond to $2J$ couplings, and triple ones - to $3J$. The same convention is used on two following pictures.

FIG. 7: “Zig-zag” and ordinary ladders. Through the middle of the ladder and parallel to it. Then, the inequality (10) gives relation between ground-state energies of the “zig-zag” ladder and ordinary one, with suitable relation between coupling constants (see FIG. 7).

5. The same construction can be applied to the “pyrochlore” ladder (see FIG. 8).
6. Ground-state energy relations for systems described in Example 4 can be repeatedly used to obtain the inequality between systems defined on triangular and rectangular lattices. Namely, consider the system defined on isotropic triangular lattice with coupling constant $J$ and with periodic boundary condition in both (“horizontal” and “vertical”) directions. Assume, moreover, that in the horizontal direction we have $2^k$ sites and $M$ in the horizontal one ($k, M$ are arbitrary). Let division of the system onto $L$ and $R$ parts will be realized by “vertical” plane in such a way that both parts contain equal number of sites. Then, by subsequent use of inequality (10), we obtain relation between ground state energies of systems on triangular lattice $E_{tr}$ and on rectangular one $E_{rect}$:

$$E_{tr} \geq E_{rect}$$

where system on rectangular lattice has coupling constants equal $J$ in the vertical direction and $2J$ in the horizontal one.

7. Analogous construction can be applied to obtain the ground-state energy inequality between systems defined on lattices: isotropic pyrochlore one ($E_{pyro}$) and rectangular one ($E_{rect}$):

$$E_{pyro} \geq E_{rect}$$

where system on pyrochlore lattice has coupling constants all equal to $J$, whereas those
on rectangular lattice has couplings $J$ in the vertical direction and $3J$ in the horizontal one.

IV. SUMMARY

In the course of paper, some extension and applications of Lieb-Schupp approach have been given. The first result concerns relaxing of demand of reflection symmetry, present in their papers. It turned out that also other kinds of symmetry are allowed (inversion, $C_2$ rotation). The second result is an application of Lieb-Schupp inequality, relating ground-state energies of various systems, to numerous new (to my best knowledge) situations. The relation between ground-state energies of models on triangular and rectangular lattices can serve as an example.

In the paper [11] Schupp wrote: “There is no doubt that the scheme can be further generalized”. I consider my paper as a step in this direction, but of course possibilities of the Lieb-Schupp scheme seem to be far from exhaustion.

APPENDIX A: APPENDIX

Here we supply proof of the inequality (5).

Proof: Using polar decomposition theorem, we can express the $u$ matrix as: $c = uc_R$, where the $u$ matrix is unitary. We have: $(uc_Ru^\dagger)^2 = uc^\dagger cu^\dagger = (uc_R)(uc_R)^\dagger = cc^\dagger = c_L^2$, then, because the (positive) square root is unique, we have: $uc_Ru^\dagger = c_L$. Analogously, for arbitrary analytic function $f$ defined on positive real numbers, we have: $uf(c_R)u^\dagger = f(c_L)$. In particular, $u\sqrt{c_R} = \sqrt{c_L}u$, which implies: $c = \sqrt{c_L}u\sqrt{c_R}$. Now, let: $P = u^\dagger \sqrt{c_L}M \sqrt{c_L}u$ and $Q := \sqrt{c_R}N^\dagger \sqrt{c_R}$; then, we have:

$$|\text{Tr} c^\dagger McN^\dagger| = |\text{Tr} PQ| \leq \frac{1}{2}(\text{Tr} PP^\dagger + \text{Tr} QQ^\dagger)$$

$$= \frac{1}{2}(\text{Tr} c_LM c_LM^\dagger + \text{Tr} c_R N c_R N^\dagger),$$

(A1)

where we have used Schwarz inequality for matrices:

$$|\text{Tr} PQ| = |\sum_{i,j} P_{ij}Q_{ji}| \leq \frac{1}{2} \sum_{i,j} (|P_{ij}|^2 + |Q_{ji}|^2) = \frac{1}{2}(\text{Tr} PP^\dagger + \text{Tr} QQ^\dagger).$$
