Introduction

Degenerative changes of the acromioclavicular joint (AC) joint are frequently seen in clinical practice in early adulthood at a time when other joints of the human body are not yet affected [6, 20, 23, 24]. Many of these have a traumatic history with a heavy fall onto the shoulder or repetitive overload such as in overhead labour or athletes [2, 15, 21, 22, 26]. Another cause is all forms of inflammatory arthritis that affect the AC joint and subsequently lead to cartilage degeneration and all stages of joint destruction [13]. The third and largest group of patients is without a history of trauma or overload and absence of inflammatory disease, but with clear signs of joint degeneration that in some patients become a source of pain and functional impairment, which then requires therapy and, in a few cases, surgical intervention.

Many of the patients in the early stages of the disease are asymptomatic, some even with advanced joint destruction [16, 23]. Conservative treatment usually starts with anti-inflammatory medication and narcotic pain medication, physiotherapy, and intra-articular injections with local anesthetics and steroids. Failed conservative therapy over a time period of weeks and months for symptomatic AC joint degeneration is the indication for surgical resection of the lateral clavicle or AC joint resection (lateral clavicle resection plus resection of the joint surface of the acromion; [14, 22]). This procedure can be performed either arthroscopically or open, with a clear preference for the arthroscopic technique, as it implies a lower risk of impairing the superior joint capsule.

Little is known about the pathophysiology of non-traumatic degenerative AC joint disease. In the authors' clinical practice, they have observed a frequent phenomenon. In a number of cases, the AC joint of affected patients seems to open up with an anterior angle and the first contact of both joint partners is at the posterior part. The objective of this study, therefore, is to investigate whether there is a typical pattern of AC joint degeneration in comparison to healthy subjects. The hypotheses are that: (1) The disease starts at the posterior part of the joint and (2) that this is accompanied by a typical pattern of malalignment of the joint surfaces.

Materials and methods

This is a retrospective monocentric diagnostic study in which healthy and affected subjects were investigated using magnetic resonance imaging (MRI) scans in the transverse plane in the period from July 2013 to December 2017. All patients signed informed consent before participation and the ethics committee approved the study (study number: 3429).

Inclusion criteria for group 1 were healthy adults with normal asymptomatic AC joints who underwent arthroscopic AC joint resection.

Exclusion criteria were all relevant pathologies or activities that affect the AC joint, such as history of trauma or previous surgery and overhead athletes.

On MRI scans in the transverse plane, the anterior, central, and posterior joint space width of the AC joints was measured. The AC angle was measured between two lines that are aligned with the joint surface of the acromion and the lateral clavicle, respectively (an anteriorly open angle defined with positive values; Fig. 1a–c).

All measurements were independently performed by the first and second authors, in a blinded fashion, on a computer using specific picture archiving and communication system (PACS) software (dicomPACSView, Version 5.2.11, Oehm and Rehbein, Rostock, Germany). Average values were used for statistical analysis.

SPSS® software (Version 25.0; IBM Corp., Armonk, NY, USA) was used for statistical analysis. Measurement values were reported as mean values ± standard deviation (SD), median, value range, and 95% confidence intervals. The normality of data was tested by visual inspection using boxplots and scatterplots and statistically using the Kolmogorov–Smirnov and Shapiro–Wilk tests. As the normality assumption was uncertain in portions of the data, the U-test according to Mann-Whitney and the Wilcoxon rank test were used to compare means of both groups.
and categorical data. The Spearman’s rank test was used to perform correlation analysis.

Inter-observer reproducibility of the measurements was quantified with the intra-class correlation coefficient (ICC) using a pair-wise correlation model with absolute agreement. The ICC was classified from fair to excellent [4, 12]. P-values below 0.05 were considered to be statistically significant.

Results

The mean age of patients in group 1 (n = 10 female) was 38.6 years (SD 16.5; range 18.0–72.0) and in group 2 (n = 43 females) 60.0 years (SD 11.0; range 18.2–84.5).

Significantly higher AC angles were observed in group 1 with 7.63 (range 0–17.2) compared to 19.2° in group 2 (range −9.8–42.7) (p < 0.001; Fig. 2; Table 1).

The joint space width in both groups was significantly smaller in group 2 compared to group 1 for the central and posterior part (p < 0.001). These differences were also observed in a subgroup analysis for gender differences between the groups (Table 2; Fig. 3).

There were no gender differences within the groups except for slightly greater values for male patients for the anterior joint space width in group 2 (6.1 mm, range 0–11) compared to female patients in group 2 (5.1 mm, range 0–9) (p = 0.033; Table 3).
Typical patterns of malalignment in the degenerative acromioclavicular joint

Abstract

Introduction. Although arthroscopic acromioclavicular (AC) joint resection is a frequently performed procedure, the pathophysiology of non-traumatic AC joint degeneration is still unclear. The purpose of this study was to investigate whether non-traumatic AC joint degeneration shows a typical pattern and whether it starts at the posterior part of the joint with malalignment of the articular surfaces.

Materials and methods. In a retrospective monocentric diagnostic study, healthy and affected subjects were investigated using T2 magnet resonance imaging (MRI) scans in the transverse plane. Group 1 included 30 healthy asymptomatic adults with no history of trauma (mean age, 38.6 years). In group 2, 90 patients with symptomatic AC joints who underwent arthroscopic AC joint resection were included (mean age, 60.0 years). All patients with relevant pathologies that affect the AC joint were excluded. Malalignment was defined as posterior joint space smaller than 2 mm in conjunction with an AC angle lower than 12°.

Results. The measured values were (mean group 1 in mm; mean group 2 in mm; p-value): anterior joint space (6.07; 5.63; 0.50), central joint space (2.97; 2.09; 0.001), and posterior joint space (3.97; 2.38; 0.001), AC angle (7.63; 19.2; 0.001). In group 1, n = 24 (80%) of subjects showed aligned AC joints, whereas in group 2, only n = 11 (12.2%) of joints were aligned (p < 0.001). Increasing age correlated significantly with malalignment (r = 0.21, p = 0.021).

Conclusions. Patients with symptomatic degenerative changes of the AC joint show a typical pattern of anterior opening of the joint with early contact of the posterior joint surfaces in contrast to healthy subjects. Increasing age influences this effect.

Typische Fehlstellungsmuster bei Akromioklavikulargelenkdegeneration

Zusammenfassung

Hintergrund. Obwohl die arthroskopische akromioklavikuläre (AK) Gelenkresektion häufig durchgeführt wird, ist die Pathophysiologie der nichttraumatischen AC-Gelenkdegeneration noch unklar. In der vorliegenden Studie wurde untersucht, ob die nichttraumatische AK-Gelenkdegeneration ein typisches Muster zeigt und ob sie am hinteren Teil des Gelenks mit einer Fehlstellung der Gelenksflächen beginnt.

Material und Methoden. In einer retrospektiv-monozentrischen Diagnostikstudie wurden gesunde und symptomatische Probanden mithilfe von T2-Magnetresonanztomographien (MRT) in der Transversalebene untersucht. Gruppe 1 umfasste 30 gesunde asymptomatische Erwachsene ohne Trauma in der Vorgeschichte (Durchschnittsalter 38,6 Jahre). In Gruppe 2 wurden 90 Patienten mit symptomatischen AK-Gelenken eingeschlossen, obwohl in Gruppe 2, nur 11 (12,2%) der Fälle (p < 0.001). Es fand sich eine signifikante Korrelation zwischen steigendem Alter und Fehlstellung (r = 0.21, p = 0.021).

Schlussfolgerung. Patienten mit symptomatischen degenerativen Veränderungen des AK-Gelenks zeigten ein typisches Muster der vorderen Gelenkkopplung mit frühem Kontakt der hinteren Gelenksflächen verglichen mit gesunden Probanden. Das Alter beeinflusst diesen Effekt.

The interrater reliability (intraclass correlation coefficient, ICC) showed moderate to good values with better agreement in the control group (r = 0.575 to 0.744) compared to the affected group (r = 0.342 to 0.624; Table 4).

Age was found to be significantly correlated for the AC angle with decreasing values with increasing age (r = −0.319, p = 0.002) and for the anterior joint space (r = −0.219, p = 0.038) only in group 2. All other measured items were not correlated with age (Table 5).

Malalignment of the AC joint was defined as a posterior joint space <2 mm and an AC angle <12°. The analysis of all patients in terms of alignment showed that only n = 11 (12%) patients showed normal alignment of the AC joint in group 2 compared to n = 24 (80%) patients in group 1 (Table 6).

Discussion

The most striking result of this study is the observation of a typical pattern of AC joint degeneration with an increase of the AC angle and reduction of the posterior joint space with early contact of the acromion and clavicle that is responsible for the painful symptoms in affected patients. Edelson et al. described a typical pattern of changes at the acromion in advanced degenerative changes of the AC joint with elongation of the joint facet in the sagittal plane principally in the posterior aspect of the acromial facet [7]. This is confirmed by the present results that the posterior contact of the distal clavicle with the acromial joint facet is a typical phenomenon in the affected pa-
tient group. It appears to be logical that, with time and continued overload accompanied by osteophyte formation in conjunction with the deformation of the bony surface, flattening of the joint surface and extension in the posterior part occurs.

This phenomenon has not been studied as yet. One explanation is the altered kinematics of the healthy scapulothoracic rhythm. This not only stresses the AC joint, but also brings the rotator cuff in conflict with the scapula, which finds its correlate in the frequently observed coexistence of both pathologies in a number of patients [3, 5]. This can be either dynamic or static and have a variety of possible effects. Frequently observed are inflexibility and stiffness of the muscles attached to the coracoid process (short head of biceps and pectoralis minor muscle) in conjunction with weakness of the muscles attached to the medial border of the scapula at the back (lower trapezius, rhomboid, and anterior serratus muscle) with loss of the stabilization effect to scapula to the thorax [10, 11]. Additionally, a change of posture and an either dynamic (modern lifestyle with sitting, working at desks, and computers, etc.) or static (degenerative changes of the thoracic spine) increasing hyperkyphosis of the thoracic spine amplify the aforementioned effects [9, 28]. The protracted scapula pushes the distal clavicle forward, but the clavicle cannot follow this route of motion since it is fixed at the sternoclavicular joint where the majority of clavicle motion occurs [19, 22, 27]. Thus, the entire clavicle can only rotate forward in a part of a circle with its length being the radius and the sternoclavicular joint being the center of rotation.

This can result in malalignment of the joint surfaces with an opening AC angle and contact of the posterior parts of the clavicle and acromion (Fig. 4).

The authors are not aware of any other study assessing the morphologic changes of degenerative AC joint disease in the axial plane and describing the joint space width in asymptomatic adult subjects [23].

Petersson et al. assessed the AC joint space in 151 patients on anteroposterior radiographs on plain films with a ruler [18]. They observed a decrease of the joint space with increasing age, but did not describe a statistical test for it. This is in contrast to the present study, in which no correlation of joint space width with increasing age was found for all patients and only a weak negative correlation was found for the anterior joint space in the affected group. This effect can be explained by a bias in patient selection in both studies. Petersson et al. do not provide any information on the clinical situation of the included patients (symptomatic vs. asymptomatic) and in the present study only 11 patients showed a pattern of joint degeneration with global joint space reduction that is too small to calculate a correlation with age.

Nicholson et al. also found an increasing number of AC joints with degenerative changes with increasing age in an analysis of 420 scapulae, but in contrast to the present study, the patient population consisted of many elderly patients. Additionally, the authors did not assess the joint space width, but made a visual judgment based on the formation of osteophytes, erosion of the subchondral bone, or the presence of eburnated bone [17].

The normal acromioclavicular joint space width is reported to be 1–3 mm [29] in a study by Zanca and 3.1±0.8 by Petersson [18] in the frontal plane on anteroposterior radiographs. One should note that many AC joints show a complex three-dimensional orientation (oblique in the frontal and axial plane) with individual variations, and the radiograph is the sum of overlap of these structures [8]. Therefore, it becomes highly likely that a distinct measurement on axial MRI scans without overlap results in higher absolute values.

It has been shown that, although advanced degenerative changes can be well visualized on anteroposterior radiography, smaller changes cannot be depicted [25]. In fact, the authors were able to show that, in a number of cases, the affected AC joints show a tendency to open up the anterior joint space and the AC angle anteriorly, which could easily be mistaken for a normal joint space on anteroposterior radiographs.

The aforementioned pathomechanism of a dynamic process starting with disturbed scapulothoracic motion leading to a typical pattern of AC joint degen-

ereation is only one possible explanation for symptomatic AC joint involvement. Direct trauma of the joint, such as in collision athletes, instability, malalignment, and degenerative changes after traumatic AC joint separation, among others, are possible causes of early joint destruction and pain. Further studies are necessary to work out more precisely possible determinants of AC joint degeneration, thereby allowing a better understanding of the disease and more specific therapy.

### Limitations

There are some limitations that need to be noted. The control group consisted of 30 asymptomatic patients. Since degenerative AC joints can remain asymptomatic especially in early phases, there is a potential selection bias [24]. A selection bias also is likely for group 2, since the decision for arthroscopic AC joint resection in this study is a clinical one based on clinical examination, history of complaints and conservative therapy, psychological burden, and radiologic signs of joint degeneration and not on radiologic signs alone.

The measurement of the distances and angles is subject to relatively high variation, as expressed by the assessment of intraobserver reliability (Table 3). This is due to the fact that the joint itself is comparatively small, the resolution on MRI scans limited, and the landmarks sometimes difficult to identify. This is aggravated by the fact that a number of patients present with a lateral clavicle joint surface that is not plane but convex or oblique, which makes identification especially of the anterior border of the joint difficult [1, 5].

The data were measured on MRI scans from different institutions and different scanners (1.5T and 3T). Although the scanning protocols are standardized, small variations must be assumed in the predefinition of landmarks for the scanning by each radiographer.

### Conclusion

This study was able to identify a typical pattern of degenerative disease of the AC joint that starts at the posterior part of the joint in the axial plane along with anterior opening of the joint due to malalignment of the clavicle in relation to the acromion. The clinical impact is that, in the case of surgical treatment, particular attention should be paid to the posterior part of the joint.
