Abstract

**Purpose:** We aimed to evaluate the usefulness of palliative radiotherapy in reducing the frequency of red blood cell (RBC) transfusions in patients with malignant tumor bleeding as a quantitative value to evaluate the hemostatic effect.

**Patients and methods:** In this study, we conducted a retrospective review of patients visiting our department between June 2013 and April 2021. All patients underwent RBC transfusions for 30 days before the initiation of radiotherapy. We determined the overall survival time and RBC transfusion-free time using statistical tests.

**Results:** In total, 21 patients were enrolled in our study, including 13 women and 8 men; the median patient age was 63 years (range: 32 to 82 years). After radiotherapy, 19 of the 21 patients had a decreased frequency of requirement for RBC transfusion compared to that before radiotherapy. Fourteen patients had achieved an RBC transfusion-free state one month after radiotherapy. The estimated 1-year overall survival and RBC transfusion-free rates were 36.3% (95% confidence interval [CI]: 14.2%) and 66.7% (95% CI: 42.5%–42.5 %), respectively.

**Conclusion:** The present study revealed a reduction in RBC transfusion after palliative radiotherapy in patients with malignant tumor bleeding. We believe that reducing the frequency of blood transfusions in patients with terminal conditions would have significant clinical benefits.

Introduction

The incidence of clinically significant tumor bleeding in patients with advanced-stage cancer is approximately 6%-14% (1). Prolonged tumor bleeding results in progressive anemia, which causes fatigue, dyspnea, shortness of breath, dizziness, and lightheadedness. Red blood cell (RBC) transfusion directly improves anemia and is a mainstay in the treatment of patients with general anemia(2). For symptom palliation in patients with advanced cancer, RBC transfusion has the potential to relieve symptoms such as fatigue and dyspnea(3). However, for patients in the terminally ill state, the impact of anemia could be further exacerbated by other underlying comorbidities, nutritional deficiencies, dietary intake, reduced functional status, and insufficient environmental support(4). Therefore, the threshold for RBC transfusion used in the general patient population is not necessarily applicable to terminal care population(5). There is an urgent need to clarify the benefits and risks of RBC transfusion in the terminal care state(6).

Since the discovery of X-rays, palliative radiation therapy has been used to relieve the symptoms of cancer for more than 100 years (7). Recent accumulating data suggest that the aggressive use of high-conformal therapy, including stereotactic ablative radiotherapy, in patients with limited metastases can not only improve symptoms but also increase disease-free and overall survival rates (8, 9). These new directions are very promising, but the conventional usage of these therapies continues to be in high demand and requires a high level of skill and expertise.
The hemostatic effect on tumor bleeding is one of the main clinical benefits of palliative radiotherapy. Several retrospective studies have revealed the high efficacy of hemostatic radiotherapy (10, 11); however, there is no consensus on the criteria for evaluating the hemostatic effect.

The present study focused on the usefulness of palliative radiotherapy in reducing the frequency of RBC transfusion in patients with malignant tumor bleeding as a quantitative value to evaluate the hemostatic effect.

**Material And Methods**

This study was conducted through a retrospective review of patients visiting our department between June 2013 and April 2021. The inclusion criteria were as follows: (i) referral to our department for palliative intent of malignant tumor bleeding, (ii) RBC transfusion requirements for 30 days before the initiation of radiotherapy, and (iii) sufficient data in medical records for assessment. Patients who lost to follow after radiotherapy only within one month were excluded.

All procedures performed in the studies involving human participants were in accordance with the ethical standards of the Declaration of Helsinki.

The study procedures were approved by our institutional review board (the Research Ethics Committee of the University of Tokyo) and written informed consent was obtained from all patients.

The present study focused on the reduction in the frequency of RBC transfusion by palliative radiotherapy in patients with malignant tumor bleeding. "pre-RT-RBC" was defined as transfusion of the required units of RBC for 30 days before the initiation of radiotherapy. "post-RT-RBC" was defined as transfusion of the required units of RBC for 30 days after the completion of radiotherapy. One unit of RBC transfusion had nominal volumes of 140 mL, which was derived from 200 mL of whole blood.

The statistical software program R was used for statistical computing and graphics. Statistical significance was set at p < 0.05. Overall survival (OS) time was defined as the time from the start of radiotherapy to the date of death from any cause. RBC transfusion-free (RBCTF) time was defined as the time from the end of radiotherapy to the date of transfusion, wherein patients who died from any cause were treated as censored cases. Wilcoxon signed-rank test was used to compare the two matched samples.

**Results**

The patient characteristics are described in Table 1. A total of 21 patients were enrolled in our study, including 13 women and 8 men, with a median age of 63 years, ranging from 32 to 82 years. For most patients, the performance status was poor at the time of palliative radiotherapy, and the median Karnofsky Performance Status was 70%. The most frequent primary disease was gynecological cancer, followed by gastrointestinal and urological cancers. The other primary diseases were melanoma and
angiosarcoma. The most frequent pathological type was adenocarcinoma, including endometrioid carcinoma, followed by squamous cell carcinoma. The median pre-RT-RBC value was 6 units, ranging from 2 to 30. The median serum hemoglobin concentration before radiotherapy was 9.6 g/dL, ranging from 4.6 to 11.1 g/dL.

Table 1
Baseline characteristics of the 21 patients who underwent radiotherapy in our study

| Characteristics                      | Number (percent) |
|--------------------------------------|------------------|
| Sex                                  |                  |
| Male                                 | 8 (38%)          |
| Female                               | 13 (62%)         |
| Age                                  |                  |
| Median (range)                       | 63 (32–82)       |
| Karnofsky Performance Status         |                  |
| 90%                                  | 4 (19%)          |
| 80%                                  | 8 (38%)          |
| 70%                                  | 5 (24%)          |
| 60%                                  | 3 (14%)          |
| 50%                                  | 1 (5%)           |
| Primary disease                      |                  |
| Gynecological cancer                 | 10 (48%)         |
| Gastrointestinal cancer              | 6 (29%)          |
| Urological cancer                    | 3 (14%)          |
| Others                               | 2 (10%)          |
| Pathological type                    |                  |
| Adenocarcinoma                       | 14 (67%)         |
| Squamous cell carcinoma              | 4 (19%)          |
| Others                               | 3 (14%)          |
| History of previous radiotherapy     |                  |
| Yes                                  | 5 (24%)          |
| No                                   | 16 (76%)         |
| Red blood cell transfusion before RT | Median (range) [Unit] | 6 (2–30) |

The treatment schedule for radiotherapy is shown in Table 2. More than half of the patients were treated with 30 Gy in 10 fractions. After radiotherapy, 19 of the 21 patients (90.5%) showed a decrease in post-RT-RBC scores compared to that pre-RT-RBC. For the entire cohort, post-RT-RBC was significantly decreased (p < 0.001), with a median value of 0 units, ranging from 0 to 6. Figure 1 presents a waterfall plot that shows the change in pre-RT-RBC to post-RT-RBC for each patient. Fourteen patients (66.7%) had achieved an RBC transfusion-free state for 30 days after the end of radiotherapy. The median serum hemoglobin
concentration after radiotherapy was 9.7 g/dL ranging from 6.7 to 10.7 g/dL, which does not have any statistically significant difference before radiotherapy (p = 0.153).

| Treatment schedule         | Number (percent) | N | age |
|----------------------------|------------------|---|-----|
| 30 Gy in 10 fractions      | 14 (67%)         | 14 | (67) |
| 20 Gy in 5 fractions       | 3 (14%)          | 3  | (14) |
| 15 Gy in 3 fractions       | 1 (5%)           | 1  | (5)  |
| 8 Gy in 1 fraction         | 1 (5%)           | 1  | (5)  |
| 8 Gy in 2 fractions        | 2 (10%)          | 2  | (10) |

The median follow-up period for all the patients was 3.5 months, ranging from 1.1 to 37.7 months. The median overall survival time was 6.4 months (95% confidence interval [CI]: 1.8–37.5) months, and the estimated 1-year OS and RBCTF rates were 36.3% (95% CI: 14.2–59.2%) and 66.7% (95% CI: 42.5–36.5%), respectively (Fig. 2, 3). No severe radiation-induced adverse events were observed during radiotherapy.

**Discussion**

This study revealed a significant improvement in the required number of RBC transfusions between pre- and post-radiotherapy. Repeated blood transfusions can result in post-transfusion iron overload syndrome, which causes iron-related toxicity as well as multiple organ damage due to iron deposition in tissues (12). A greater number of transfused units is also a risk factor for febrile non-hemolytic transfusion reaction, which is an immune reaction of recipient antibodies reacting to donor-derived antigens (13). Moreover, transfusion itself imposes a load on the respiratory and circulatory systems and causes transfusion-related acute lung injury and/or transfusion-associated circulatory overload (14). In clinical practice, Sirianni et al. reported that transfusions in palliative care units were infrequent because of the lack of definitive evidence about its utility (15). Considering this background, we believe that reducing the frequency of blood transfusions would be of great benefit to patients in palliative care.

Surgical intervention to remove bleeding tissues or ligate blood vessels is the most direct method of treatment for tumor bleeding. However, this form of intervention is often technically difficult due to the abnormal structure of the tumor and the general condition of the patient being not good enough to withstand surgery. Therefore, careful patient selection is essential (16). Krouse et al. insisted that patients and their families who underwent surgical intervention in the palliative care unit should be aware of the risks of high morbidity and mortality (17).

Trans-arterial embolization, the intentional blocking of arteries with small particles or mechanical devices, is another treatment modality used as a palliative treatment to reduce bleeding. It is also used as a palliative treatment to reduce pain associated with symptomatic bone metastases (18). Although the
embolization procedure has been used to treat bleeding from many tumor sites with excellent results, there are potential limiting factors such as the inability to access the vessel of the tumor with a catheter owing to its location and degree of invasion(19, 20). There are also risks such as damage to peripheral organs and the possibility of ischemic organ damage. Post-embolization syndrome is characterized by fever, nausea and vomiting, and flu-like symptoms caused by an immune response to necrotic tissue, which may last for several days after embolization(21). Therefore, patients should be provided with adequate explanation about this procedure by an interventional radiology specialist.

Endoscopic treatment has proven to be effective for bleeding from the gastrointestinal tract, lungs, and bladder(22, 23). This method has the advantage of being able to see the bleeding site directly, allowing for both diagnostic biopsy and therapeutic intervention. The bleeding site can be treated by clipping, thermal cauterization, laser coagulation, or topical application of thrombin or fibrinogen(24). This technique targets only organs that can be reached endoscopically and is associated with endoscopic pain and distress with only mild sedation.

Systemic agents such as octreotide, vitamin K, vasopressin, tranexamic acid, and aminocaproic acid are used in the treatment of malignant bleeding(25). In patients with poor performance status, these drug administrations are less invasive procedures; however, their efficacy is very limited(26). Complementary procedures, such as discontinuation of anticoagulants and antiplatelet agents, may also be employed.

The present study has some limitations. The primary limitation is the small sample size, which might affect the reliability of the results, with a higher risk of several types of bias. The second limitation is the treatment heterogeneity in the radiotherapy schedule, such as total dose and fractionation. Third, our results were obtained based on the information present in the medical records of our hospital, which might have been imperfect to yield detailed information about the patients, such as physical condition and comorbidity.

In conclusion, the present study revealed a reduction in the frequency of RBC transfusion after palliative radiotherapy in patients with malignant tumor bleeding. We believe that reducing the number of blood transfusions in patients with terminal conditions would have significant clinical benefits. Therefore, future studies on this topic are warranted to elucidate the efficacy and safety of palliative radiotherapy.
