cephalosporinases, usually only AmpC (9). Nevertheless, we hypothesize that E. cloacae complex contains genotypes with epidemic potential associated with increasing rates of carbapenem resistance observed in the VHA.

The scope of this study did not include molecular characterization, so we could not determine emerging genotypes or detect outbreaks at individual facilities. Also, non-uniform susceptibility testing and interpretation throughout the VHA may affect reporting of CRE. Although criteria for interpretation of carbapenem susceptibility changed during the past decade, the revised breakpoints do not appear to have a major effect on resistance rates in Klebsiella and Enterobacter spp, according to other surveillance data (10). Despite these limitations, the VHA may serve as a vantage point for detecting nationwide trends in antimicrobial drug resistance. Integration of susceptibility testing with molecular characterization at the VHA may help elucidate the changing epidemiology of CRE in the United States.

DOI: http://dx.doi.org/10.3201/eid2305.162041

To determine the potential role of vertical transmission in Zika virus expansion, we evaluated larval pools of periorally infected Aedes aegypti and Ae. albopictus adult female mosquitoes; ≈1/84 larvae tested were Zika virus–positive; and rates varied among mosquito populations. Thus, vertical transmission may play a role in Zika virus spread and maintenance.
Following the 2007 outbreak in Micronesia, Zika virus (Flaviviridae, Flavivirus) has continued to expand its distribution throughout the Pacific region and, since 2014, the Americas (1,2). The virus is primarily maintained by horizontal transmission between Aedes aegypti mosquitoes and humans, yet other Aedes spp. are also competent vectors (3). The extent to which Zika virus can utilize vertical transmission between mosquitoes (i.e., transmission from an infected adult female mosquito to her progeny) has not been adequately assessed after peroral infection. Such studies are required to accurately determine the potential role of vertical transmission in Zika virus expansion and maintenance.

Although previous studies have found that other flaviviruses, including West Nile (4), dengue (5), yellow fever (6), and St. Louis encephalitis (7), can undergo vertical transmission, such transmission is generally relatively inefficient, with filial infection rate (FIR) estimates ranging from 1/36 to 1/6,400 (8). A previous study estimated rates for Zika virus vertical transmission in Aedes aegypti mosquitoes to be 1/290, yet a reliable estimate for transmission in Zika virus vertical transmission in Aedes aegypti mosquitoes was not achieved (8). In addition, these estimates were based on intrathoracic inoculation of Zika virus rather than on assessment after infectious blood meal acquisition.

We exposed laboratory colonies of Aedes aegypti mosquitoes (collected in Posadas, Argentina, or Poza Rica, Mexico) and Aedes albopictus mosquitoes (obtained from Suffolk County, New York) to Zika virus through infectious blood meals and evaluated the mosquitoes’ capacity to transmit the virus to progeny. For this study, we used the Zika virus strain ZIKV HND (Honduras 2016, GenBank accession no. KX906952), passaged once on C6/36 cells, and Zika virus PR (Puerto Rico 2015, GenBank accession no. KX087101.3), passaged 4 times on Vero cells and twice on C6/36 cells. Zika virus was propagated on C6/36 cells for 4 days, and freshly harvested supernatant was mixed 1:1 with sheep blood (Colorado Serum Company, Denver, CO, USA) and 2.5% sucrose.

Infectious blood meals were offered to 4- to 7-day-old female mosquitoes, and weekly noninfectious blood meals were offered after the first oviposition. Eggs laid during the second oviposition and beyond were collected and hatched for subsequent testing. Third- to fourth-instar larvae were collected in pools of 5 and processed by homogenization and centrifugation. After RNA extraction, we used Zika virus–specific quantitative reverse transcription PCR (9) to determine adult infection (indicated by positive bodies), dissemination (indicated by positive legs), viral load, and  |

### Table. Vertical transmission of Zika virus in Aedes spp. mosquitoes

| Species/population | Zika virus strain | Cycle | Blood meal titer, log_{10} PFU/mL | % Infected (diss)† | Mean body titer, log_{10} PFU/mL | Total no. pools | No. individual mosquitoes | ZIKA virus positive | FIR‡ (95% CI) |

¶Data for both mosquito populations are combined.
FIR, which was calculated by using a maximum-likelihood estimate (PoolInfRate 4.0; Centers for Disease Control and Prevention, Atlanta, GA, USA).

We tested 104 *Ae. aegypti* pools; 6 were Zika virus–positive, indicating a FIR of 11.9 (range 4.9–24.6; Table). This value equates to a ratio of $\approx 1:84$, which is substantially higher than that found by Thangamani et al., as well as ratios historically measured for flaviviruses (4–8). Although just 17 pools of *Ae. albopictus* were tested, 1 pool was positive, which equates to a similar FIR (11.8 [range 1.7–134.8]; Table) and establishes that *Ae. albopictus* mosquitoes are capable of vertical transmission of Zika virus in the laboratory.

Although the bypassing of the midgut during inoculation generally results in higher levels of vertical transmission, we fed mosquitoes high virus doses ($8.9–9.3 \log_{10}$ PFU/mL), resulting in $>93\%$ of disseminated infections and development of high viral titers in individual mosquitoes, averaging 7.1 (*Ae. albopictus*) to 7.5 (*Ae. aegypti*) $\log_{10}$ PFU/mosquito (Table). Although the likelihood that eggs were derived from mosquitoes with disseminated infections is high, the rate of vertical transmission (proportion of infected mosquitoes transmitting to progeny) could not be determined. Future studies assessing infection status and FIR of individual mosquitoes will help clarify the extent of individual variability in vertical transmission efficiency. In addition, we tested larvae rather than adults, and it is likely that transtadiol transmission is not completely efficient, so further studies are required to fully evaluate transmission potential of adults infected via vertical transmission. We observed a trend of increasing vertical transmission with flaviviruses (Table) and establishes that *Ae. aegypti* mosquitoes are capable of vertical transmission of Zika virus in the laboratory.

The construction of the Wadsworth Center Arbovirus Laboratory insectary facilities was partially funded by the National Institutes of Health (NIH) grant C06-RR-17715.

Dr. Ciota is deputy director of the Arbovirus Laboratory, Wadsworth Center, New York State Department of Health. His primary research interests are arbovirus evolution and vector–virus interactions.
