Entropy bounds applied to a system of $N$ species of light quantum fields in thermal equilibrium at temperature $T$ are saturated in four dimensions at a maximal temperature $T_{\text{max}} = M_{\text{Planck}}/\sqrt{N}$. We show that the correct setup for understanding the reason for the saturation is a cosmological setup, and that a possible explanation is the copious production of black holes at this maximal temperature. The proposed explanation implies, if correct, that $N$ light fields cannot be in thermal equilibrium at temperatures $T$ above $T_{\text{max}}$. However, we have been unable to identify a concrete mechanism that is efficient and quick enough to prevent the universe from exceeding this limiting temperature. The same issues can be studied in the framework of AdS/CFT by using a brane moving in a five dimensional AdS-Schwarzschild space to model a radiation dominated universe. In this case we show that $T_{\text{max}}$ is the temperature at which the brane just reaches the horizon of the black hole, and that entropy bounds and the generalized second law of thermodynamics seem to be violated when the brane continues to fall into the black hole. We find, again, that the known physical mechanisms, including black hole production, are not efficient enough to prevent the brane from falling into the black hole. We propose several possible explanations for the apparent violation of entropy bounds, but none is a conclusive one.

I. INTRODUCTION

Entropy bounds seem to imply that $N$ light quantum fields cannot be in thermal equilibrium at an arbitrarily high temperature. In four dimensions they are saturated at a temperature equal to $T_{\text{MAX}} = M_P/N^{1/2}$ (here $M_P$ is the Planck mass). When entropy
bounds are saturated it is possible, in many cases, to identify a physical mechanism that enforces them. The prime candidate for such a mechanism is black hole (BH) production. If many BH’s are produced, the system goes into a kind of phase transition. In the new phase the previous energy and entropy estimates are no longer valid. Since BH’s are more efficient in storing entropy, the bounds are not violated.

We seek a physical mechanism that places an upper bound on the temperature, if such an upper bound indeed exists. Since we wish to use semi-classical methods and avoid the quantum regime, we focus on the limit of large $N$ since then $T_{MAX} \ll M_P$. As we will show, the correct context for studying this issue is a cosmological context.

Previously, Bekenstein [1] argued that if the entropy of a visible part of the universe obeys the usual entropy bound from nearly flat space situations [2], then the temperature is bounded and therefore certain cosmological singularities are avoided. More recently, there have been several discussions following a similar logic. Veneziano [3] suggested that since a BH larger than a cosmological horizon cannot form [4], the entropy of the universe is always bounded. This suggestion is related, although not always equivalent, to the application of the holographic principle [5] in cosmology [6, 7, 8, 9, 10, 11, 12, 13, 14, 15]. In [16, 17, 18] it was argued that the Hubble parameter $H$ is bounded by entropy considerations, $H \leq H_{MAX} \equiv \frac{M_P}{\sqrt{N}}$. In a cosmological context this is equivalent to $T \leq T_{MAX}$.

The AdS/CFT correspondence [19, 20] offers an alternative route and a new perspective for the study of a system of a large number $N$ of light fields in thermal equilibrium in a cosmological setup by studying brane propagation in an AdS-Schwarzschild background [21, 22, 23, 24, 25]. Branes moving in AdS-Schwarzschild space are expected to be dual to finite temperature CFT’s in a cosmological background [26, 27]. However, the status of the conjecture is somewhat weaker than the one relating to an AdS space without a brane (see, for example, [28, 29, 30]). In this particular case the branes in AdS-Schwarzschild are conjectured to be dual to a radiation dominated FRW universe, which is exactly the setup that we are interested in. As we will show, the maximal temperature $T_{max}$ has a geometric 5D interpretation: it corresponds to the brane “just” reaching the BH horizon.

The conjectured duality between branes propagating in AdS-Schwarzschild space and a radiation dominated FRW universe offers a novel perspective for studying the saturation of the entropy bounds at $T_{MAX}$. The issue becomes whether the brane can continue to fall into the BH and continues to be dual to a CFT in a cosmological background at temperatures
above $T_{MAX}$.

A possible way of viewing the propagation of branes in AdS-Schwarzschild is the following: a thermal system with a known form of entropy is thrown into a BH, a process analogous to the Geroch process. Here a 4D universe is thrown whole into a 5D BH, and so issues concerning the generalized second law (GSL) and its relation to entropy bounds can be addressed. As in the standard case, it is then possible to compare the total entropy of the system before and after and to discuss cases in which a decrease in the total entropy is suspected. We do indeed find that the GSL is violated as the brane falls into the BH.

In section II we explain the saturation of entropy bounds at $T_{MAX}$, and discuss possible physical mechanisms that may lead to this saturation. In section III we discuss the issue from a 5D perspective, and discuss possible physical mechanisms that may alter the propagation of branes with respect to naive expectations. In section IV we offer several possible resolutions of the puzzle that we have posed in the previous sections.

II. BLACK HOLE CREATION AND A MAXIMAL TEMPERATURE IN FOUR DIMENSIONS

Consider a relativistic gas in thermal equilibrium at a temperature $T$. We assume that the gas consists of $N$ independent degrees of freedom in a box of macroscopic linear size $R$, we further assume that $R$ is larger than any fundamental length scale in the system, and in particular $R$ is much larger than the Planck length $R \gg l_P$. The volume of the box is $V = R^3$. Since the gas is in thermal equilibrium its energy density is $\rho = N T^4$ and its entropy density is $s = N T^3$ (here and in the following we systematically neglect numerical factors). As explained previously, we are interested in the limit of large $N$.

Under what conditions is this relativistic gas unstable to the creation of BH’s? The simplest criterion which may be used to determine whether an instability is present is a comparison of the total energy in the box $E_{Th} = N T^4 R^3$ to the energy of a BH of the same size $E_{BH} = M_p^2 R$. The two energies are equal when $T^4 = 1/N M_p^2/R^2$. So thermal radiation in a box and a BH of the same size have the same energy if

$$(TR)^4 = \frac{1}{N} M_p^2 R^2.$$  \hspace{1cm} (1)$$

Another criterion that may help us to determine the presence of an instability to BH’s
creation is to compare the thermal entropy $S_{\text{Th}} = N T^3 R^3$ to the entropy of the BH $S_{\text{BH}} = M_P^2 R^2$. They are equal when $T^3 = 1/N M_P^2 / R$. So thermal radiation in a box and a BH of the same size have the same entropy if

$$(TR)^3 = 1/N M_P^2 R^2.$$  \hspace{1cm} (2)$$

From eqs. (1) and (2) it is possible to conclude the well known fact that for fixed $R$ and $N$, if the temperature is low enough the average thermal energy is not sufficient to form BH’s. For low temperatures the thermal fluctuations are weak and they do not alter the conclusion qualitatively.

Here we are interested in the case $RT > 1$ which means that the size of the box is larger than the thermal wavelength $1/T$. The case $RT < 1$ has been considered previously in \[31\]. In this case the temperature is not relevant. Instead, the field theory cutoff $\Lambda$ was shown to be the relevant scale. In \[31\] we found a relationship between $\Lambda$, $M_P$ and the number of fields $N$ which is somewhat different than what we find here between $T$, $M_P$ and $N$.

Imagine raising the temperature of the radiation from some low value for which condition (1) is not satisfied to higher and higher values such that eventually condition (1) is saturated. Note that since $TR > 1$ eq. (1) is saturated before eq. (2). We assume that the size of the box $R$ is fixed during this process (the number of species $N$ is also fixed), and estimate the backreaction of the radiation energy density on the geometry of the box to determine whether the assumption that the geometry of box is fixed is consistent. To obtain a simple estimate we assume that the box is spherical, homogeneous and isotropic. Then its expansion or contraction rate is given by the Hubble parameter $H = \dot{R}/R$, which is determined by the 00 Einstein equation $H^2 M_P^2 = N T^4$. However, if eq. (1) is satisfied then $1/R^2 M_P^2 = N T^4$, and therefore $HR \sim 1$. The conclusion is that if eq. (1) is saturated then the gravitational time scale is comparable to the light crossing time of the box, and therefore it is inconsistent to assume that the box has a fixed size which is independent of the energy density inside it.

The conclusion from the previous discussion is that we need to study the issue of stability or instability to the creation of BH’s in a box filled with thermal radiation in a time-dependent setting, namely, in a cosmological setting, where

$$H^2 M_P^2 = N T^4.$$  \hspace{1cm} (3)$$

Entropy bounds such as the Hubble entropy bound and others are saturated if $S_{Th} =$
\[ N T^3 H^{-3} = S_{BH} = M_{Pl}^2 H^{-2}. \]

From eq. (3) we understand that this happens for
\[ H = T, \quad T = T_{\text{MAX}} = \frac{M_P}{\sqrt{N}}. \tag{4} \]

Let us examine in more detail the physics of a radiation dominated (RD) universe at temperatures near \( T_{\text{MAX}} \). If \( H = T \), the cosmological horizon size \( H^{-1} \) becomes comparable to the wavelength of a typical particle of the relativistic gas, \( \lambda \sim T^{-1} \). If we go beyond this temperature, the classical description of the particles that compose the gas in terms of a homogeneous and isotropic fluid is no longer appropriate, and thus neither is eq. (3).

Alternatively, one can think of \( T_{\text{MAX}} \) as the temperature at which the Jeans length of a typical thermal fluctuation becomes comparable to the thermal wavelength, thus suggesting, again, that the approximation of the gas by a homogeneous and isotropic fluid becomes inappropriate. Yet another way to think about \( T_{\text{MAX}} \) is as the temperature at which the entropy within a thermal wavelength becomes comparable to the entropy of a BH of the same size, thus making BH entropically favored over single particle excitations. Similarly, at \( T = T_{\text{MAX}} \) the thermal energy inside a “box” of size \( H^{-1} \), \( E = N T^4 H^{-3} \) is equal to the energy of a BH of the same size, and also the free energies of both states become comparable. All of the above supports the qualitative conclusion that a state of \( N \) degrees of freedom cannot be in thermal equilibrium at temperatures above \( T_{\text{MAX}} \). We will try to examine this issue more quantitatively below.

Let us first close some possible loopholes in our analysis. One possible loophole could have been if thermal fluctuations were too large. This is not the case. The ratio of the energy in thermal fluctuations,
\[ \frac{\Delta E^2}{E^2} = \frac{1}{N} \frac{1}{T^3 R^3}, \tag{5} \]
is small compared to the average value of the energy in this regime and is much smaller than unity for \( RT > 1 \), and \( N \gg 1 \). Another possible loophole could have been, as in [31], a clash with the assumption that the semiclassical treatment is valid. Since, in the case at hand, the energy is dominated by the mean value of \( \rho \), and not by the fluctuations, we do not have problems with black hole evaporation: in fact it turns out that for
\[ T \leq T_C = \sqrt{\frac{640\pi}{N}} M_P \tag{6} \]
BH’s can be treated classically and, as can be seen by inserting the correct numerical factors into the definition of \( T_{\text{MAX}} \), \( T_{\text{MAX}} < T_C \).
In any case, it is clear that at $T_{MAX}$ a significant change must occur in the way we describe thermal equilibrium and the assumption that we can treat gravity as semiclassical, only providing matter with a geometric background. All these considerations are well known in the case $N = 1$; but if $N$ is a large number the relevant scale can be much smaller than the Planck scale.

We would like to discuss the issues in a more quantitative way. We would like to estimate the time scale for the collapse of perturbations which, if frequent and strong enough, will lead to production of black holes. The perturbation equations which govern their evolution are well known \[32\]; we present here the equation governing the dynamics of the Bardeen potential $\Phi$, in longitudinal gauge

$$6\ddot{\Phi} + 24\dot{H}\dot{\Phi} + 12(\dot{H} + H^2)\Phi - 2\Delta\Phi = 0,$$

with $H \equiv \dot{R}/R$, the dot denoting the derivative with respect to conformal time $\eta$, and $\Delta$ the spatial Laplacian operator. The solution of the perturbation equations is quite standard. First, by means of the spatial Fourier transform the Laplacian operator is expressed in terms of the comoving wavenumber $k$ as $\Delta \to -k^2$. Then one notices that, since the background evolves as a power law in conformal time, and, in particular, for a radiation dominated contracting universe one has $R(\eta) \sim -\eta$, with $-\infty < \eta < 0$, the solution for the mode $\Phi_k$ can be expressed in terms of the variable $x \equiv k\eta$ as:

$$\Phi_k(\eta) = A_k F(x),$$

where $F(x)$ (whose explicit form is not needed here) scales as $x^{-2}$ for $x \to -\infty$, diverges as $x^{-3}$ for $x \to 0$, and is of order one for $x \sim -1$.

The factor $A_k$ can be determined through the perturbed Friedmann equation which gives a relation between the Bardeen potential and the density perturbation:

$$\Phi_k(\eta) = \frac{3}{2x^2} \frac{\delta\rho_k(x)}{\rho}.$$  \hspace{1cm} (9)

We now observe that the thermal energy fluctuations are dominated by the comoving wavenumber $k_T \equiv RT$ since the higher modes are exponentially suppressed in the Boltzmann distribution, and that we can estimate them via eq. \[5\]. We further observe that at the time $\eta_{MAX}$ when the critical temperature $T_{MAX}$ is attained, one has $x = -1$ for the mode that dominates the fluctuations. By combining all these elements we may express the
Bardeen potential at $\eta_{MAX}$ in terms of an initial thermal fluctuation at some early time $\eta_i$:

$$\Phi_{kT}(\eta_{MAX}) = \frac{3}{2} \frac{1}{\sqrt{N}} \frac{1}{(RT)^{3/2}} \frac{1}{x_i^2} F(-1).$$  \hspace{1cm} (10)$$

The factor $x_i^2 F(x_i)$ is of order one, and so is $F(-1)$; this leads us to the conclusion that the Bardeen potential is still small at the critical time, due to the large factor $\sqrt{N} (RT)^{3/2}$ in the denominator.

To summarize, we have found that if the initial perturbations are provided by thermal fluctuations, then their initial amplitude is very small, and since they grow only as a power law, they do not have enough time to become large before the critical temperature is reached. We conclude that BH production from thermal perturbations is not quick enough, so entropy bounds seem to be violated.

At this point we cannot proceed further with semiclassical methods and get a better idea on the state of a system when the temperature is increased beyond $T_{MAX}$, or even whether this is possible at all.

III. FEEDING A 4D BRANEWORLD TO A 5D BLACK HOLE

We can gain some insight about the meaning of $T_{MAX}$, and perhaps some further technical control by modelling a 4D RD universe as a brane moving in an AdS$_5$-Schwarzschild spacetime.

For precision, we will take the following representation for the bulk spacetime

$$ds^2 = -H(R)dt^2 + \frac{1}{H(R)}dR^2 + R^2 d\Omega_3^2,$$  \hspace{1cm} (11)

where $H(R) = 1 + \frac{b^2 L^2}{R^2} - \frac{b^4 L^2}{R^2}$ vanishes at the black hole horizon $R_H$ and $b = \left( \frac{8G N^3}{3\pi M L^2} \right)^{1/4}$, $M$ being the black hole mass. $L$ is related to the cosmological constant of the AdS and also to the brane tension $\lambda$, which is tuned in such a way as to make a vanishing effective cosmological constant on the brane. Note that the line element in eq.(11) describes only the part of spacetime outside the BH horizon; this will become important and relevant shortly when we discuss the fate of a brane that is about to fall into the BH.

For the AdS/CFT correspondence to be valid, $b$ must be large $b \gg 1$ \[26\], that is, the black hole must be large and hot compared to the surrounding $AdS_5$. In this limit the closed
4D universe can be treated as flat, and we can write $R_H \simeq bL$, and $b \simeq \pi LT_0$, where $T_0$ is the Hawking temperature of the black hole.

The motion of the brane through the bulk spacetime is viewed by a brane observer as a cosmological evolution. According to the prescription of the RS II model [33], the 4D brane is placed at the $Z_2$ symmetric point of the orbifold. On the other hand, in the so called mirage cosmology [22], the brane is treated as a test object following a geodesic motion. In both cases the evolution of the brane in the AdS$_5$-Schwarzschild bulk mimics a FRW radiation dominated cosmology. Thus, both prescriptions are useful for our purposes. We will keep them in mind in the following discussion.

The brane can be described by its radial position as a function of the proper time of the brane $R_b(\tau)$. The evolution of $R_b(\tau)$ is determined by an effective Friedmann equation:

$$\left(\frac{\Dot{R}_b}{R_b}\right)^2 = \frac{b^4L^2}{R_b^2} - \frac{1}{R_b^4},$$

(12)

where the dot here stands for a derivative with respect to cosmic time. Since, as we recall, $b \gg 1$ so that the curvature term is always negligible, we ignore it in the following. Eq. (12) expresses the dynamics of the brane in terms of 5D quantities; we now focus on the case of a contracting brane and translate those quantities into 4D ones in order to be able to compare eq. (12) with eq. (3).

The AdS/CFT correspondence tells us that the number of species in the CFT is given by $N = L^3/G_N^{(5)}$, while the 4D and the 5D Newton’s constants are related by $LG_N^{(4)} = G_N^{(5)}$ (again, we consistently ignore numerical factors). This is enough to make a comparison between eq. (12) and eq. (3) and to obtain the temperature measured on the brane as $T = b/R_b$, which is also in accordance with the AdS/CFT correspondence. In passing, we notice that one should not confuse the temperature of the boundary CFT that is dual to the AdS bulk theory with the Hawking temperature of the AdS BH as measured by a bulk observer located at the coordinate $R$. The latter is given by $T_0/\sqrt{H(R)}$ and scales with $R$ in a similar way to the CFT temperature only in the asymptotic limit $R \to \infty$.

We now wish to see what happens in the 5D picture when the limiting temperature is approached on the brane. By expressing $M_P \equiv \sqrt{G_N^{(4)}}$ and $N$ in terms of 5D quantities we can see that $T_{MAX} \simeq 1/L$ and, since the corresponding value for $R$ is $b/T_{MAX}$, we find that

$$T \to T_{MAX} \implies R_b \to R_H.$$

(13)
$T_{\text{MAX}}$ is reached exactly when the brane reaches the BH horizon and is about to enter into the black hole!

At this point the whole meaning of the AdS/CFT correspondence becomes unclear since, as we have noted before, it is valid only for the region outside the BH horizon. In the RS II picture the brane represents the boundary of the bulk spacetime, which means that beyond the brane at $R > R_b$ there is an identical copy of the bulk spacetime at $R < R_b$. So, as the brane reaches and then crosses the horizon, namely after $R_b$ (the position of the brane) has become less than $R_H$ (the horizon), the 5D spacetime is described by two identical copies of the interior region of an AdS-Schwarzschild space, cut at $R = R_b$ and glued together, with the brane placed at the $Z_2$ symmetry point. At this point the 5D BH disappears, and it is not clear which brane CFT should be the dual of the bulk theory.

One could imagine avoiding confusion about the interpretation of the AdS/CFT correspondence when the brane reaches the BH horizon if the brane motion is interpreted according to the “mirage” prescription. In this case, the brane is not the boundary of spacetime. Rather, it is a probe brane moving through the fixed bulk background. This approach is slightly more helpful in our case. A reasonable interpretation of what transpires at horizon crossing is that the 4D universe simply ends its existence and disappears into the BH. The BH “eats” the 4D universe, its mass increases and so does its size, and entropy. Therefore the final state from a 5D point of view is simply an $AdS_5$-Schwarzschild space with a larger BH.

We are thus studying a process analogous to the Geroch process, with the significant difference that, in the case at hand, an entire universe is thrown into the BH. Therefore we can look at the entropy balance during the process and see whether the GSL is respected or not.

In order to have a vanishing effective cosmological constant on the brane, one has $G_N^{(5)} \lambda \simeq L^{-1}$; this means that at horizon crossing the total energy of the brane is

$$E|_{R=R_H} \simeq \frac{b^3 L^2}{G_N^{(5)}}.$$  \hspace{1cm} (14)

Comparing $E$ to $M \simeq \frac{b^4 L^2}{G_N^{(5)}}$ we see that for $b \gg 1$ the total energy of the brane is much smaller than the BH mass $E \ll M$.

The entropy of the 5D black hole is $S = \mathcal{A}(R_H)/4G_N^{(5)}$, with the area of the horizon given by $\mathcal{A}(R_H) = 2\pi^2 R_H^3$. When the brane falls into the BH, the entropy of the BH is increased
by the following amount:

$$\delta S \approx \frac{1}{4G_N^{(5)}} E \delta A(R_H(M)) \delta M \approx \frac{EL^2}{R_H} \approx \frac{EL}{b}. \quad (15)$$

For the GSL to hold, the total entropy of the system should increase in the process

$$\delta S > S_b. \quad (16)$$

Since $S_b = 2\pi^2 R_H^3 N T^3 \approx EL$ is the total entropy on the brane when it is about to fall into the BH, we find that for the total entropy to increase

$$b < 1. \quad (17)$$

However, for the AdS/CFT correspondence to hold, $b$ has to be much larger than unity $b \gg 1$! If indeed $b \gg 1$, then apparently the GSL is violated in this process. We have thus found that a violation of the GSL in the 5D bulk corresponds to a violation of the entropy bounds in the 4D brane. The situation is completely analogous to the one discussed in connection with the ordinary Geroch process where the GSL is apparently violated if the falling object does not satisfy the Bekenstein bound. This issue has a long history (see, for example, [2], [35]-[40]) and is controversial to some extent. We do not attempt to take sides in the debate, but rather to simply point out the similarities.

In any case, if the previous interpretations are correct, we must conclude that the AdS/CFT correspondence seems to be incapable of describing a RD universe in thermal equilibrium at temperatures above $T_{MAX}$; in the mirage approach this happens because the brane that hosts the CFT disappears, while in the RS II picture it is the other way around: the 5D BH ceases its existence. In both cases, this sudden breaking of the correspondence lends support to the significance of $T_{MAX}$ as a temperature above which thermal equilibrium physics is altered.

We may try to use the 5D picture to understand in a more qualitative way what is the physical mechanism that renders $T_{MAX}$ a limiting temperature. Black hole creation and the subsequent “breaking” of the brane seemed to be one of the possibilities in the 4D picture. From the brane world point of view this would correspond to the formation of “blisters” on the brane. In fact, since the temperature of the brane scales as $1/R_b$, if a piece of brane is closer to the BH with respect to the rest of the brane, then the local temperature on that piece will be higher, as will its energy density. A piece of the brane that has higher energy
density has a higher local magnitude of the Hubble parameter. Therefore the speed at which it falls towards the BH is increased, and we expect a “blister” to form on the brane. Thus a local oscillation of the brane position would be seen by a brane observer as a local density perturbation which is further amplified as the brane falls towards the BH. This mechanism can be studied by looking at perturbation equations for the position of the brane. Since these are coupled to the bulk metric perturbations of the AdS$_5$, it seems that the full set of perturbation equations must be studied.

However, as it turns out, in our case one can study the perturbations directly from the 4D brane point of view: it is sufficient to write down the projected Einstein equations on the brane as

$$G_{\mu\nu} = -E_{\mu\nu},$$

Eq. (18) looks so simple because there is no matter on the brane, just the tension which is fine-tuned in order to cancel the bulk cosmological constant, so that both disappear from the dynamics. The only effective source term is then the projection of the bulk Weyl tensor, which we parameterize as a fluid with energy density $\rho_e$ and pressure $p_e = -\rho_e/3$ ($E_{\mu\nu}$ is traceless). Thus the system of perturbation equations is closed and can be solved without reference to the 5D picture. Notice that this happens because of the simplicity of the model at hand: if we had some matter on the brane this would no longer have been true.

In the end, the perturbation equations look exactly the same as in the pure 4D scenario discussed in the previous section and the same physical considerations about the growth of perturbations are valid. So it seems that the standard picture is confirmed: as $R \rightarrow R_H$, $H \rightarrow T$, and at horizon crossing the typical modes in the thermal bath become unstable. However their growth follows a power law only, and thus there is not enough time for the instability to invalidate the whole picture.

Another possible 5D mechanism that could modify our discussion and its conclusion about the saturation of the entropy bounds is the interaction of the bulk Hawking radiation with the brane. Since, as we have seen, the temperature of the Hawking radiation diverges at the horizon, one might have expected that at some point the Hawking radiation pressure becomes so high that it prevents the brane from falling into the BH. Perhaps the Hawking radiation pressure could cause the brane to bounce back and change its contraction into expansion or
cause it to float just above the horizon. We think that this is unlikely. However, clearly the
issue deserves further study, especially in light of the fact that for $b \gg 1$ the temperature of
the Hawking radiation is also very large. For boxes falling into BH’s the issue was debated
extensively in the context of the relationship between the GSL and entropy bounds \[35\]-\[40\].

We would like to make a few observations about the possible influence of the Hawking
radiation on the motion of the brane.

First, in AdS space the geometry provides a confining environment for the radiation
which is then in equilibrium with the BH. Notice also that, unlike the pure Schwarzschild
case, here the equilibrium is stable. The pressure on the brane results from the difference
in the force exerted on the two sides of the brane. If the system is in thermal equilibrium
and the brane is moving through the radiation fluid, then the pressure on it depends on
the interaction of the brane with the radiation. If it is transparent, then the radiation does
not exert any pressure on the brane, and if it is opaque, then the radiation pressure can be
estimated by the pressure of a fluid at the Hawking temperature.

The Hawking temperature at the position of the brane is given by $T_H = T_b/\sqrt{H(R_b)} \simeq\frac{b}{L\sqrt{H(R_b)}}$. Substituting $H(R_b) = 1 + \frac{R^2}{L^2} \left(1 - \frac{b^4L^4}{R_b^4}\right)$, we see that as long as the distance of the
brane from the horizon $R_b - bL$ remains finite, then $T_H \sim b/R_b \sim T_{brane}$. We then observe
that the Hawking radiation pressure is smaller by a factor of $\mathcal{N}$ compared to the pressure
on the brane, which in turn determines the acceleration of the brane towards the BH. We
conclude that as long as the distance of the brane from the horizon is not particularly small,
the Hawking radiation pressure is not likely to alter its motion significantly.

When the brane does get close to the BH it seems that the Hawking radiation pressure
can affect the motion of the brane. However, it is not clear whether the fluid description of
the Hawking radiation is valid in the vicinity of the horizon. The wavelength of a typical
particle in thermal bath at temperature $T$ is $\lambda \sim T^{-1}$, and the typical wavelength of the
Hawking radiation in our AdS-Schwarzschild spacetime is

$$\lambda_H(R) \sim \frac{\pi L}{b} \sqrt{\frac{R^2}{L^2} - \frac{b^4L^2}{R^2}} ; \quad (19)$$

where we have taken into account the behavior of the local Hawking temperature as discussed
above.

On the other hand the physical distance of a spacetime point with radial coordinate $R$
from the horizon is

\[ d(R) = \int_{bL}^{R} \sqrt{g_{RR}(x)} \, dx = \frac{L}{2} \log \left[ \frac{(R/bL)^2}{\sqrt{(R/bL)^4 - 1}} \right]. \tag{20} \]

Notice that although \( g_{RR} \) diverges near the horizon, \( d(R) \) is always finite at finite \( R \).

Now observe that as one gets close to the horizon (i.e. for \( R - bL \ll bL \)), the following relation holds

\[ \lambda_H(R) \rightarrow 2\pi d(R), \tag{21} \]

meaning that the typical wavelength \( \lambda_H \) becomes larger than (or in any case, of the same order of magnitude as) the physical distance from the horizon, thus implying that the description of the Hawking radiation as a fluid becomes inappropriate at this point. One could then argue that the Hawking radiation forms mostly at distances \( d \sim bL \) from the black hole and larger, and that for smaller distances there is no significant radiation pressure. This means that Hawking radiation pressure cannot stop the brane from falling into the BH as it approaches the horizon.

These issues were discussed in the context of falling boxes most recently by Marolf and Sorkin [40], and previously by others. We conclude that the answer depends on the detailed dynamics of the system.

\[ \text{IV. DISCUSSION AND POSSIBLE RESOLUTION} \]

We have seen that a special value of the temperature \( T_{MAX} = M_P/\sqrt{N} \) emerges in various contexts. We have seen that such a value arises in four dimensional models as the temperature at which entropy bounds are saturated, and in five dimensional models as the effective induced temperature on a brane propagating in AdS-Schwarzschild spacetime as it reaches the horizon of the bulk BH and is about to disappear into it. We have also shown that in the five dimensional picture the GSL is violated as the brane falls into the BH.

We have presented some examples for the appearance of this special value of the temperature, and have provided arguments supporting its existence or that a change in the description of equilibrium physics at this temperature is required. We have not provided conclusive evidence as to whether a specific physical mechanism is responsible for enforcing such a maximal temperature, or whether one exists at all. We have not been able to identify
a single mechanism that is efficient and quick enough to prevent the universe from exceeding the limiting temperature nor to identify the required changes in the description of physics at this temperature.

We list a few possibilities which we leave as unsolved puzzles and interesting problems for future research:

1. Entropy bounds give the correct limiting temperature in their currently known form. Some enforcing mechanism exists which is still unknown.

2. Entropy bounds need to be modified such that the limiting temperature disappears, and they are consistent at all temperatures.

3. Brane world AdS/CFT correspondence is valid for the model that we are considering: that the brane falls into the BH and entropy bounds are violated.

4. Brane world AdS/CFT correspondence in this particular context is not valid when the brane approaches the horizon and falls into the BH. When modified appropriately, for example by correctly taking into account the influence of the Hawking radiation pressure or the growth of perturbations or the effects of additional induced matter on the brane, entropy bounds remain valid in their currently known forms.

5. Both the AdS/CFT correspondence in this specific context and the currently known entropy bounds are not valid for temperatures of about \( T_{MAX} \).

6. The number of light fields \( \mathcal{N} \) is fundamentally limited, a fact which is well represented by entropy bounds, and therefore considering the large \( \mathcal{N} \) limit \( \mathcal{N} \to \infty \), as is done in the AdS/CFT correspondence, is incorrect.

At this point in time we do not have a clear preference or a clear indication from our calculations as to which of these possibilities is correct. We hope that future research will help to resolve the issues that we have discussed.

V. ACKNOWLEDGMENTS

This research was supported in part by the Israel Science Foundation under grant no. 174/00-2 and by the NSF under grant no. PHY-99-07949. S. F. was partially supported by
the Kreitman foundation. R. B. thanks the KITP, UC at Santa Barbara, where this work was completed. We thank the participants of the string cosmology program at KITP for comments and D. Marolf in particular for discussions and helpful suggestions.
