Objective: The aim of this study was to evaluate the validity and reliability of using static surface electromyography (sEMG) on persons with neck pain and in healthy adults.

Design: Cross-sectional study.

Methods: Twenty-two female participants with neck pain and thirty healthy adults in the age group of 20-65 years were recruited in this study. To evaluate the validity and reliability of sEMG in subjects with neck pain, the subjects’ characteristics were recorded and the Visual Analog Scale (VAS) and Neck Disability Index (NDI) were examined in addition to sEMG and algometer tests being carried out on the subjects. The site for using the sEMG and algometer was the upper trapezius. sEMG test-retest reliability was measured by intraclass correlation coefficients (ICCs). Independent t-tests were used to analyze the differences in the dependent variables between subjects with neck pain and healthy adults. The Pearson correlation coefficient was used to examine the linear relationship between measured variables.

Results: sEMG and algometer tests were reliable according to the test-retest reliability results in subjects with neck pain and healthy adults (ICC=0.815-0.979). The results of this study showed that there were significant differences in respect to age, VAS, sEMG and algometer tests between persons with neck pain and healthy adults (p<0.05). The VAS and NDI were statistically correlated with sEMG and algometer results (p<0.05).

Conclusions: In this study, we investigated the clinical usefulness of the static sEMG test in evaluating the pain scale of persons with neck pain with high reliability and validity.

Key Words: Diagnosis differential, Diagnostic techniques and procedures, Electrodiagnosis, Neck injuries

Introduction

Seventy-one percent of the world’s population has a high incidence of experiencing neck pain at least once in their lifetime. It has confirmed that 45.5% of a total of 512 workers in the office have complaints of neck pain, and in 50%-85% of those with neck pain, 47% have chronic symptoms in which the symptoms are not completely resolved [1]. Patients with pain often complain of subjective symptoms, such as muscle stiffness and tension along with pain, and the main clinical symptoms lead to an imbalance of the soft tissues around the neck and shoulders, and painful areas on the neck, shoulder, back, scapula, fatigue headaches, and restriction of range of motion, but in severe cases, it is associated with functional disability of the neck, such as muscle weakness, muscle atrophy, and muscle tension, depending
on the site of the nerve root lesion [2]. In clinical practice, to measure the degree of disability and quality of life in relation to the pain of the neck, the Neck Disability Index (NDI) Questionnaire, the Visual Analog Scale (VAS), and the Numerical Rating Scale Subjective measurements are generally used [3]. However, since these instruments cannot quantify pain objectively, electromyography (EMG) is used to measure the muscle activity of a specific muscle and a pressure gauge is used to analyze the threshold of pain [3].

Recently, studies have been conducted to analyze pain levels by observing the voltage level and directional pattern of the spinal muscles using the muscular electrical resistance of static surface EMG (sEMG) [4]. Static sEMG is a surface electrode scanner that records electrical resistance in resting and active states by characterizing the electrical potential of a particular muscle [5]. Using the same technology as electrocardiogram and EMG, the muscle tension level of wide muscles is recorded using single or multiple electrodes which are very sensitive to movement. The relatively low frequency band and low signal degradation function represent the muscular muscle tension level as a bar-shaped stress score [6, 7]. In particular, static sEMG is a tool for evaluating muscle tension, which is used in persons with back pain symptoms such as spasms, tenderness, limited range of motion, postural disorders, intervertebral disc disease, soft tissue damage, and neuromuscular disorders, and it is used as a diagnostic tool for patients with motor control disorders [5]. In addition, static sEMG diagnoses muscle imbalance, identifies the underlying causes of pain, and confirms the function and condition of the spinal nerve muscles of the patient [7].

In previous studies, there were statistically significant correlations between static contraction and pain in the resting state and static contraction of patients with chronic cervical pain using sEMG, but there was no significant correlation in the resting state [8]. As a result of examining the correlation between muscle activity, pain intensity, and dysfunction of the neck and chest by providing neck movement tasks to patients with chronic cervical pain and normal persons, there was a significant correlation between muscle activity and dysfunction in persons with neck pain [9]. Needle EMG used in previous studies have caused pain during examinations and surface electromyograms were mostly used on subjects with muscle activity values analyzed during an active state. Therefore, static sEMG tests are considered to be more useful for visualizing the muscular signals from a resting state. Static sEMG showed high reliability in the test-retest measurements of spinal fatigue [10] and it exhibited reliability and validity in distinguishing healthy and back pain patients [11]. However, static sEMG has been studied mainly in patients with back pain, and there is a lack of research on the relationship with the evaluation tools used to evaluate pain in clinical practice.

Therefore, the purpose of this study was to determine the reliability of the test method by analyzing the difference between static sEMG and the pressure gauge of each subject in order to test the usefulness of the static sEMG test method for assessing those with cervical pain and healthy adults. In addition, this study was conducted to evaluate the relationship between static sEMG results, the VAS, the NDI, and the pressure gauge system. In this study, if the reliability and validity of static sEMG can be verified, it could be suggested as a useful measurement tool for the assessment of cervical pain.

**Methods**

**Subjects**

This study was conducted between September 30th and October 27th, 2018 and included a total of 52 patients with 22 female patients between the ages 20-65 year old who had been diagnosed with neck pain from a neurologist in Daejeon Raphael Neurology, and 30 healthy adults.

Those who have sustained cervical pain for more than 3 months, have been diagnosed with a cervical pain from a specialist, and have complained of unilateral pain that is consistent with the patient’s pain site were included while those with orthopedic problems, neurological injuries, and serious surgical injuries were excluded.

For healthy adults, those with a score of 15 or less on the NDI questionnaire were selected while those with orthopedic problems, neurological injuries, and serious surgical injuries were excluded. In order to distinguish between non-malignant and non-malignant tumors, persons with a score of 15 or less on the NDI questionnaire were selected, and those with orthopedic problems, neurological injuries, and serious injuries were excluded. In addition, all subjects provided their informed consent after the explanation of the purpose and procedures of this study were given. This study was approved by the Institutional Bioethics Committee of Konyang University (IRB No. KYU-2018-091-01).

**Measurement**

The general characteristics of subjects (age, height, and
weight), VAS, NDI, static sEMG, and algometer results were examined. The assessment site was located at the site of the upper trapezius muscle to the midpoint between the seventh cervical vertebrae and the acromion process where static sEMG and pressure goniometry was performed on both sides [12]. The examination time for each subject was approximately 20 minutes. The subjects were allowed to rest for 15-20 minutes before the start of the examination process.

**Visual Analog Scale**

The VAS is used to determine the subjective pain level of the patient. On a 10-cm line, the left end represents a state of no pain at all (0 point), and the right end refers to the maximum pain intensity (10 points) [13,14].

**Neck Disability Index**

The NDI is the most commonly used questionnaire to assess cervical spine anomalies and was originally developed to assess the severity of everyday life in persons with severe cervical pain, especially for patients with whiplash trauma [15]. The NDI has 10 items with a total score of 50 points. The lower the score, the lower the degree of dysfunction. The intraclass correlation coefficient (ICC) value of the test-retest reliability of this instrument is 0.93, and the Cronbach alpha value is 0.82 [15].

**Static surface electromyography**

Static sEMG was performed with the Myovision EMG 4000 (Precision Biometrics/Myovision, San Carlos, CA, USA). Static sEMG is a wireless device consisting of two joysticks with five electrodes, each of which is designed to record muscle activity levels at the vertebral level where the joystick is located [16]. As a non-invasive device, static sEMG signals are quantified and the actual data is measured in mV and recorded on the monitor, indicating the amplitude of muscle activity during the measurement time [16]. This equipment uses a frequency filter of 20-500 Hz and the band-pass filter is used to maximize the continuous range and reduce the possibility of false negatives. The range of scanning is 0.08-200 mV [7]. Prior to the assessment, the electrode containing the disposable aseptic conductive medium was pressed onto the pad on which the joystick was placed, and hair was removed from the assessment site, and the skin was cleansed with an alcohol wipe. The assessment was performed with the subject in sitting position in a chair with the hip and knee joints flexed to 90° and hands placed onto the knees while looking straight ahead [17]. The measurement site was from the upper trapezius to the midpoint between the seventh cervical vertebrae and the acromion process where joystick electrodes were placed on the top of both right and left sides, which were evaluated simultaneously.

The mean value was obtained from three consecutive measurements from each assessment site (Figure 1).

**Algometer**

The Commander Algometer (JTECH Medical, Salt Lake City, OH, USA) was used to evaluate the pressure sensitivity of the pain site. The pressure gauge system is an objective pain assessment method, which is useful for measuring pain points using pressure thresholds, and can quantify the exact location of the pain and the pressure sensitivity of the muscles [18]. The algometer consists of a measuring instrument, a knob, and a recorder. When the strap connected to the recorder is worn on the wrist, the knob is grasped with one
hand, and the pressure is applied vertically to the measuring point at a rate of 1 kg/s [12]. The measuring instrument was 1 cm² in diameter and after the time the subject cried ‘Oh’ with pressure application, which indicated the start of the pain sensation, the pressure reading was recorded (Figure 2). The posture and position of the measurement site were the same as those for the static sEMG, and the average of the results were obtained from three measurements per site (Figure 2) [12].

Figure 2. Static surface electromyography device and measurement sites (upper trapezius).

Table 1. General characteristics of subjects (N=52)

| Group                | Age (y)     | Height (cm) | Weight (kg) | Visual Analog Scale |
|----------------------|-------------|-------------|-------------|---------------------|
| Neck pain subjects (n=22) | 33.59 (10.29) | 161.60 (4.49) | 55.77 (9.38) | 5.65                |
| Healthy adults (n=30)    | 20.87 (1.07)  | 160.72 (4.67) | 56.93 (9.19) | -                   |
| t (p)                  | −5.775 (<0.001) | −0.685 (0.496) | 0.448 (0.656) | -                   |

Values are presented as mean (SD).

Table 2. Tests of Static sEMG and algometer values in subjects with neck pain and healthy adults—test-retest reliability measurements (N=52)

| Division   | Measuring site | Intraclass correlation coefficient (Neck pain subjects (n=22)) | Intraclass correlation coefficient (Healthy adults (n=30)) |
|------------|----------------|----------------------------------------------------------------|---------------------------------------------------------|
| Static sEMG| Left           | 0.867                                                            | 0.861                                                    |
|            | Right          | 0.848                                                            | 0.815                                                    |
| Algometer  | Left           | 0.977                                                            | 0.959                                                    |

sEMG: surface electromyography.

Statistical analysis

Statistical analysis was performed using PASW Statistics ver. 18.0 (IBM Co., Armonk, NY, USA). Test-retest reliability was calculated by ICCs. An independent sample t-test was conducted to compare the measurement variables between the two groups. Pearson correlation coefficients were used to determine the linear relationship between measured variables. All statistical significance levels were below $p=0.05$.

Results

General characteristics of the subject

As for general characteristics of the subjects, there were 22 subjects with cervical pain and 30 healthy adults who had participated in this study. The average values for the patients was 33.59±10.29 years old for age, 161.60±4.49 cm for height, 55.77±9.38 kg for weight, and 5.65 for the VAS. The average values for the characteristics of healthy adults was 20.87±1.07 years old for age, 160.72±4.67 cm for height, and 56.93±9.19 kg for weight. There was no significant difference in height and weight among the subjects, but there was a significant difference in age ($p<0.05$) (Table 1).

Reliability analysis

In the analysis of the test-retest reliability of the static sEMG and pressure gauge system in the subjects with neck
pain and healthy adults, the reliability of the static sEMG and pressure gauge showed ICC values of 0.815-0.979, which indicated a high level of reliability (Table 2).

Comparison of the Neck Disability Index, static surface electromyography, and pressure difference

There was a significant difference in NDI, static sEMG, and pressure gauge system values between persons with neck pain and healthy adults (p<0.05) (Table 3).

Correlation analysis

The VAS showed a statistically significant correlation with the static sEMG (r=0.540) and the pressure gauge system (r=0.543). The NDI was significantly correlated with static sEMG (r=0.380) and pressure gauge (r=0.615). Table 4 shows that there was no statistically significant correlation between the static sEMG and the pressure threshold.

Discussion

In order to evaluate the usefulness of static sEMG in persons with neck pain, this study examined a total of 52 subjects, which included 22 subjects with neck pain and 30 healthy subjects. The reliability of the test method was verified by analyzing the difference of the static sEMG and pressure threshold test of all the subjects, and as the general characteristics of the patients with neck pain and healthy adults, VAS, NDI, static sEMG results were obtained, the purpose of this study was to investigate whether if static sEMG is a useful tool for measuring pain levels.

Results showed that the test-retest reliability of the static sEMG and pressure gauge system was ICC=0.815-0.867, indicating high reliability, and it was confirmed that the pressure gauge system was a highly reliable evaluation tool with ICC=0.956-0.979. The results of the study on the reliability of the static sEMG were similar to the results of previous studies.

Dedering et al. [19] stated that the use of EMG to examine for erector spinae muscle fatigue in subjects with low back pain had a high test-retest reliability of ICC=0.85. A study by Cid et al. [20] found that the reliability of the EMG results for maximal contraction activity of the trapezius muscle in subjects with neck pain and healthy adults was high with ICC=0.97 and also suggested that sEMG is helpful in examining muscle contraction activities.

In addition, Mohseni Bandpei et al. [10] described static sEMG as a useful technique for distinguishing between back pain patients and healthy subjects in the assessment of muscle fatigue using sEMG for patients with back pain and healthy subjects.

The results of this study suggest that static sEMG may help to provide prompt and accurate information in the initial assessment of pain in the evaluation of pain according to muscular electrical resistance.

Fejer and Hartvigsen [21] stated that the percentage of patients with neck pain was 34.6% at 21-49 years of age, 27.3% at 50-71 years of age, and increased to 19.8% at 18-29 years of age with a rate of 16.4% at 30-44 years of age. This is similar to the age of the subjects in this study. Static sEMG signals were significantly increased to twice the amount in subjects with neck pain compared to healthy adults (p<0.05).

Ambroz et al. [7] measured the muscle activity patients with chronic back pain using static sEMG and found that it was 3 times higher. In addition, a study by Nederhand et al. [22]
was conducted to investigate the relationship between the upper traps muscle activity of patients with neck dysfunction and normal subjects using sEMG. The mean difference between the subjects was 0.8 for static activity and 3.9 to 8.1 for dynamic activity. The patients with neck disability showed higher scores on muscle activity. Similar results were obtained in this study.

Bittmen and Cram [23] suggested that since static sEMG measures the tone of muscles, it can objectively document muscle spasm or other muscle anomalies in the pain area, and it is suggested that muscle relaxation or stretching exercises can be proposed as a technique to treat muscle spasms.

Significant increases in pressure thresholds were observed in subjects with neck pain compared with healthy adults (p<0.05). Cho et al. [24] showed that the pressure threshold of the patient over 12 months was significantly higher than that of the patients within 12 months, and the pain threshold was significantly higher in patients with pain compared to healthy subjects.

Ashton-Miller et al. [25] have shown that pain and decreased muscle strength leads to a decrease in proprioception, leading to a rise in pressure threshold, which is consistent with our study.

The purpose of this study was to analyze the relationship between static sEMG, pressure thresholds, VAS, and NDI in order to investigate the correlation between static sEMG and pain assessment tools.

One of the most common and useful methods of evaluating the neck pain is the VAS and the NDI, which were significantly correlated with the parameters of the static sEMG and the pressure thresholds. Castro Sánchez et al. [26] found that the pressure threshold value also changed corresponding to the VAS before and after the intervention in the study of the effects of acupuncture treatment on pressure tenderness threshold, quality of life, pain intensity, and depression in patients with myofascial pain syndrome. In addition, in Korea, it has been reported that there was a significant correlation between pressure thresholds of the painful muscle with the VAS (r=-0.175) [25]. A study by Oliveira et al. [27] showed that there was a strong linear correlation between the VAS and static sEMG when some functions were analyzed in order to find an objective sEMG equipment that could be related to the lower extremity. The area of the EMG signal was positively correlated with the intensity of the electrical stimulation causing the pain (r=0.99), and the EMG signal was correlated with subjective pain. Although the measurement sites were different, the results were similar to the results of this study.

In the study by Jung and Kim [28], muscle contraction of the left and right trapezius muscles were significantly correlated with cervical dysfunction, as measured by a comparison of cervical dysfunction and EMG muscle contraction (p<0.05). These results are consistent with the hypothesis that muscle weakness is caused by sustained epidemiological stress, weakening muscle strength increases the structural instability of the neck, and is associated with pain in the neck. There was a correlation between the state of the muscle signal measured by sEMG and the NDI, which may indicate pain [28]. However, this study did not show a significant correlation in the relationship between static sEMG and algometer results. Sommerich et al. [29] showed that even if sEMG electrodes were properly positioned on the specific muscle to be measured, if the electrode was placed so that it spanned the nerve distribution point of the muscle, it is considered that there may have been a problem associated with other locations. Therefore, even if the pain area was measured by static sEMG, it is considered that the pain threshold is not correlated with the pressure threshold, and the number of samples is small. Therefore, further studies on this are warranted on this subject.

This study had some limitations. The number of subjects in the study population was relatively low, and it is difficult to apply the research results general population since the results had been obtained from patients with neck pain, and there were limitations in the ability to control various life-style factors (habits, psychological state, exercise habits) that could have affected the research result. In addition, it was not easy to fixate the static EMGs and therefore, it was not possible to measure the dynamic variables of the subjects. In the future, these limitations should be addressed, and pain evaluation and analysis study of static sEMG in dynamic tasks and various pre- and post-interventional studies are necessary.

The purpose of this study was to investigate the clinical usefulness of static sEMG in evaluating pain objectively and to provide the basic data of static sEMG equipment for persons with neck pain and healthy adults. It was confirmed that static sEMG is a reliable tool that can be useful in verifying the patient’s pain level.
