Supporting Information

ABSTRACT: Many potential applications of monolayer transition metal dichalcogenides (TMDs) require both high photoluminescence (PL) yield and high electrical mobilities. However, the PL yield of as prepared TMD monolayers is low and believed to be limited by defect sites and uncontrolled doping. This has led to a large effort to develop chemical passivation methods to improve PL and mobilities. The most successful of these treatments is based on the nonoxidizing organic “superacid” bis(trifluoromethane)sulfonimide (TFSI) which has been shown to yield bright monolayers of molybdenum disulfide (MoS₂) and tungsten disulfide (WS₂) but with trap-limited PL dynamics and no significant improvements in field effect mobilities. Here, using steady-state and time-resolved PL microscopy we demonstrate that treatment of WS₂ monolayers with oleic acid (OA) can greatly enhance the PL yield, resulting in bright neutral exciton emission comparable to TFSI treated monolayers. At high excitation densities, the OA treatment allows for bright trion emission, which has not been demonstrated with previous chemical treatments. We show that unlike the TFSI treatment, the OA yields PL dynamics that are largely trap free. In addition, field effect transistors show an increase in mobilities with the OA treatment. These results suggest that OA serves to passivate defect sites in the WS₂ monolayers in a manner akin to the passivation of colloidal quantum dots with OA ligands. Our results open up a new pathway to passivate and tune defects in monolayer TMDs using simple “wet” chemistry techniques, allowing for trap-free electronic properties and bright neutral exciton and trion emission.

KEYWORDS: Tungsten disulfide, ligand passivation, photoluminescence, mobilities

Transition metal dichalcogenides (TMDs) are a class of layered materials which have garnered intense research interest due to their unique optical, electronic, and catalytic properties.¹–³ TMD bulk crystals consist of monolayers bound by weak van der Waals interactions, which can be overcome via dry mechanical cleavage (e.g., scotch tape method)⁴ or via liquid phase exfoliation.⁵,⁶ Also there are numerous ongoing efforts to directly grow highly crystalline few or monolayer TMD films in particular by chemical vapor deposition (CVD).⁷,⁸ Many of these materials show a transition from indirect bandgap in the bulk material to a direct bandgap in the monolayer limit.¹,² The direct band gap, high absorption coefficient, and potentially high carrier mobilities of TMD monolayers hold great potential for optoelectronic applications such as photodetectors, light emitting diodes (LEDs), and photovoltaics.² Reduced dielectric screening in TMD monolayers in contrast to the bulk crystal gives rise to tightly bound excitons at room temperature.³,⁶ This provides an interesting arena to study many-body exciton–exciton and exciton–carrier interactions that result in diverse multiexciton¹³,¹² and charged exciton species¹³,¹⁴ respectively.

A number of potential applications of TMDs, such as in optoelectronic devices, quantum light sources, or on-chip quantum information processing,¹⁵–¹⁷ are dependent on having materials of high optical quality. In particular, there is a need for materials with high photoluminescence quantum efficiencies (PLQE) and also tunable emission properties. This raises a fundamental challenge for TMDs because exfoliated or CVD-prepared monolayers show extremely low PLQE, typically ~0.001–5%.¹⁸,¹⁹ There have been various proposals for the cause of the nonradiative exciton recombination such as trion formation,²⁰ the presence of chalcogen vacancies,²¹ or other atomic substitutions.²²,²³ However, the exact nature of the defects and the mechanism by which they quench PLQE is
This has led to a number of treatments being proposed to enhance the PLQE of monolayer TMDs, most commonly MoS$_2$ and WS$_2$. For instance, studies have sought to improve PL via surface treatments using electron withdrawing dopants such as 2,3,5,6-tetrafluoro 7,7,8,8-tetracyanoquinodimethane (F$_4$TCNQ) and hydrogen peroxide. Monolayer deposition of titanyl phthalocyanine (TiOPc) as a charge transfer interface also increases PL yield in MoS$_2$. These are proposed to reduce electron density, suppressing low PLQE trion formation therefore promoting neutral exciton recombination. Other studies have sought to preserve the intrinsic optical properties of TMDs via exfoliation onto hexagonal boron nitride (hBN) or hBN encapsulation, which isolates monolayers from doping and disorder induced by the underlying substrate (e.g., Si–SiO$_2$). This has been shown to result in more uniformly distributed dominant neutral exciton PL with narrow homogeneous spectral line width free of substrate effects, which otherwise manifest as inhomogeneous contributions in monolayer TMD PL spectra. Whereas hBN encapsulation improves overall optical quality, a large increase in PL at low excitation intensities has not been demonstrated. Hoshi et al. have demonstrated that hBN encapsulation suppresses exciton–exciton annihilation rates in monolayer WS$_2$ as indicated by large PL enhancement at high excitation intensities compared with nonencapsulated monolayers. Most notably, surface treatment with nonoxidizing organic “super acid” bis(trifluoromethane)sulfonimide (TFSI) has been shown to yield very bright PL from monolayer MoS$_2$ and WS$_2$. Although the exact mechanism of the PL enhancement is still debated, it has been shown that the TFSI treatment reduces the extent of n-type behavior in MoS$_2$, which is consistent with the observed suppression of trion formation. The authors of ref 21 have recently demonstrated PL enhancement and exciton dynamics similar to TFSI-treated MoS$_2$ and WS$_2$ via electric gating. The application of a negative bias is said to dedope the intrinsically n-type materials, which suppresses trion formation thus enhancing radiative recombination of the neutral exciton. By comparing the exciton dynamics of TFSI-treated and gated TMDs, the authors conclude that TFSI acts as an electron drawing species which suppresses trion formation. However, it has been shown that the TFSI treatment leads to trap-limited PL dynamics and does not give rise to improved mobilities in field-effect transistors. In addition, the harsh nature of TFSI necessitates additional fabrication steps to protect commonly used electrode materials such as nickel. Lastly, although treatments like the TFSI boost neutral exciton PL they do not lead to bright trion emission, which would be of use in applications such as optical readout of trions for spintronics. Thus, an alternative benign chemical treatment that simultaneously improves PL and mobilities while easing device fabrication would provide an attractive means to functionalize and passivate monolayer TMDs. Here, we demonstrate that a simple long-chain acid, oleic acid (OA) can greatly enhance the PL of monolayer WS$_2$ yielding bright neutral exciton emission comparable to TFSI treated monolayers. In addition, OA allows for bright trion emission and an increase in field effect mobilities. We also show that in comparison to previous TFSI treatment, where PL is trap limited, the OA treatment yields predominantly trap free PL characteristics. Our demonstration that a weak acid can be used to passivate and tune the properties of monolayers WS$_2$ draws parallels to the surface treatment of inorganic colloidal quantum dots, such as cadmium sulfide (CdS) and lead sulfide (PbS), where long-chain acids and in particular OA are used to passivate surfaces, and thus opens a range of
options for passivating and tuning the properties of monolayer TMDs.

Figure 1a,c shows the scatter plots of spectral position of the peak emission and peak PL counts extracted from PL maps of multiple WS₂ monolayers on Si-SiO₂ (90 nm) before and after surface treatment with OA and TFSI respectively. Maps were measured at 135 W cm⁻². Figure 1b,d shows representative PL spectra for points which correspond to the median PL intensity of an exemplary monolayer before and after treatment. Median enhancement factors, Δmedian, of 40× and 9× were calculated for OA and TFSI treatment, respectively. Table 1 shows key statistics that accompany PL enhancement, namely, average enhancement across the monolayers (Δave), that is, the ratio of post- and pretreatment peak PL counts; standard deviation in PL intensity (σcounts), average emission peak wavelength (λave), and standard deviation in peak wavelength (σλ). The untreated case is indicated by (∗) where appropriate. The data presented in Figure 1 and Table 1 were derived from non-fitted raw PL spectra.

For the data collected, the OA treated samples show a higher average enhancement factor compared to TFSI treated samples. The standard deviation in PL intensity, σcounts, reveals that TFSI treatment results in a more spatially homogenous brightness, as compared to the OA case. Better spectral uniformity is achieved with OA treatment as quantified by ∼58% reduction in σλ compared with a ∼40% reduction in σλ with TFSI. The spectral narrowing in OA-treated monolayers is potentially due to changes in strain induced by ligand coordination. The statistical data derived from the PL maps clearly reveals that the OA treatment significantly improves the PL of the WS₂ monolayer.

In order to understand the exciton dynamics which underpin the PL enhancement with the OA treatment, we study the excitation intensity-dependent PL of the monolayers. Figure 2a–d shows the results derived from a room-temperature steady-state excitation intensity dependence series over 4 orders of magnitude to give insight into recombination regimes present in the samples. Because of experimental limitations, the excitation power was limited to low (0.018–0.3 W cm⁻²) and high (110–5820 W cm⁻²) regimes, making sure to remain below 9000 W cm⁻² to avoid thermal damage.39,24

Figure 2a shows noticeable changes in spectral shape with increasing excitation intensity in the pristine monolayer. The spectra appear to broaden and red shift. This spectral red shift with increasing excitation intensity in pristine monolayers has been attributed to trion (X⁻) formation, which occurs as a result of binding between excess charges in the conduction band from photoionized native n-dopants and neutral excitons (X).40 With large binding energies of the order of tens of millielectronvolts due to reduced screening in monolayers, these quasi-particles can be observed and studied at ambient conditions.13 The perceived red shift and spectral broadening as a function of excitation intensity is caused by the contributions of trions alongside excitons. The close overlap between the excitons and trions makes deconvoluting the spectra challenging, which prevents resolution of the relative

| Treatment | Δave | σcounts | λave | σλ |

*Characteristics prior to treatment marked with (∗).
contribute to spectral broadening, which in this case appears to be more present on quartz. For clarity, the normalized spectra are shown in SI Figure 6.

Figure 2b shows comparable data for the OA treated monolayer. In the high excitation intensity regime ($10^5-10^7$ W cm$^{-2}$) in addition to the neutral exciton peak (which does not shift in energy), a red-shifting peak, $\zeta$, emerges. The well separated $\zeta$-feature enables spectral fitting with Gaussians as shown in Supporting Information (SI) Figure 1. Figure 3f shows the increasing ratio of $\zeta$-peak intensity to the neutral exciton (X) as a function of excitation intensity, which is a notable characteristic of trion (X') emission. SI Section 1 provides further description and brief analysis of results acquired from spectral fits. Figure 3c shows the spectra for the TFSI-treated sample, where the single narrow emission peak throughout the series indicates dominant neutral exciton recombination, which is consistent with what has been reported in ref 21.

Figure 2d shows a log–log plot of the PL intensity dependence as a function of excitation intensity for each sample. Under low power excitation, the brightness of the OA treated sample is comparable to the TFSI treated sample. The gradients of the series in the two regions give insight into the treated sample is comparable to the TFSI treated sample. Under low power excitation, the brightness of the OA treated monolayer. In the high excitation intensity regime ($10^5-10^7$ W cm$^{-2}$) in addition to the neutral exciton peak (which does not shift in energy), a red-shifting peak, $\zeta$, emerges. The well separated $\zeta$-feature enables spectral fitting with Gaussians as shown in Supporting Information (SI) Figure 1. Figure 3f shows the increasing ratio of $\zeta$-peak intensity to the neutral exciton (X) as a function of excitation intensity, which is a notable characteristic of trion (X') emission. SI Section 1 provides further description and brief analysis of results acquired from spectral fits. Figure 3c shows the spectra for the TFSI-treated sample, where the single narrow emission peak throughout the series indicates dominant neutral exciton recombination, which is consistent with what has been reported in ref 21.

Figure 2d shows a log–log plot of the PL intensity dependence as a function of excitation intensity for each sample. Under low power excitation, the brightness of the OA treated sample is comparable to the TFSI treated sample. The gradients of the series in the two regions give insight into the recombination regimes present. The gradient values are the gradients of the series in the two regions give insight into the treated sample is comparable to the TFSI treated sample. Under low power excitation, the brightness of the OA treated monolayer. In the high excitation intensity regime ($10^5-10^7$ W cm$^{-2}$) in addition to the neutral exciton peak (which does not shift in energy), a red-shifting peak, $\zeta$, emerges. The well separated $\zeta$-feature enables spectral fitting with Gaussians as shown in Supporting Information (SI) Figure 1. Figure 3f shows the increasing ratio of $\zeta$-peak intensity to the neutral exciton (X) as a function of excitation intensity, which is a notable characteristic of trion (X') emission. SI Section 1 provides further description and brief analysis of results acquired from spectral fits. Figure 3c shows the spectra for the TFSI-treated sample, where the single narrow emission peak throughout the series indicates dominant neutral exciton recombination, which is consistent with what has been reported in ref 21.

When treated with OA, an enhancement in PL under low intensity comparable to the TFSI case is evident but with a power law exponent close to the pristine case ($m_1 = 1.1$). The $\gamma$-ratio increases only slightly, indicating predominant radiative neutral exciton directly from the band edge in the low intensity regime. At high laser intensities, the power law diminishes more drastically than the pristine case ($m_2 = 0.62$). As previously discussed for Figure 2b,f at higher excitation intensity there is a large contribution of trions to its overall emission. Given the inherently lower PLQE of trions compared to neutral excitons, the reduction in overall radiative recombination rate due in part to trion generation in the high power regime is plausible. In effect, a combination of exciton–exciton annihilation, trion generation, and any persisting defect related nonradiative decay mechanisms should account for the overall reduction in $\gamma$ seen in the OA treated sample.

Interestingly, the TFSI treated sample shows superlinear ($m_1 = 1.45$) behavior and increasing $\gamma$-ratio (i.e., relative PLQE) at low intensity. This manifests itself as a dependence of the relative PLQE on excitation intensity, as seen in Figure 2e. The study by Goodman et al. on long-lived trapped excitons in defect states best explains this observed superlinear behavior. At the low end of the low intensity regime, a proportion of excitons decay from traps to the ground state over a long period ($\sim \mu$s). These long-lived low energy transitions form part of the tail-end region of the PL spectra. Available ambient thermal energy at room temperature statistically favors detrapping for a significant proportion of trapped excitons, which return to the band edge and recombine radiatively to the ground state. With increasing excitation, density traps become saturated causing any further excitations to recombine radiatively directly from the band edge. Hence, the superlinear behavior and increasing $\gamma$-ratio in the low intensity regime characterizes the process of trap state filling prior to predominant radiative recombination where the effective PLQE ($\gamma$) saturates. The diminishing $\gamma$-ratio in the high-intensity regime signifies the onset of exciton–exciton annihilation.

To explore the photophysics of the treatment further we turn to time-resolved PL microscopy. Figure 3a shows normalized time-resolved signal of untreated and treated samples at room temperature under low power excitation (0.67 W cm$^{-2}$). Biexponential decay fits best describe the decay dynamics observed with a fast component $\tau_1$ and a slow component $\tau_2$. The fast decay ($\tau_1 \sim 64$ ps) of the pristine sample indicates a pronounced onset nonradiative recombination at early times, consistent with the intrinsically low PLQE. The OA and TFSI-treated samples show a signal growth beyond the instrument response function (IRF) region. Although the exact nature of this growth in the PL signal is...
sharp reduction in $\tau$ as a function of $n$ of low PLQE trions, as seen in Figure 2b, will contribute to the concentrations. At higher excitation intensities the formation of excitation$^-$exciton annihilation. OA-treated sample implies nontrap limited movement of monolayer WS2, with average increases higher than TFSI-treated sample (Fig. 3b). As carrier concentration increases, trap states are filled giving rise to dominant radiative recombination from the band edge as indicated by the saturated $\tau_1$ value. The reduction in $\tau_1$ at high carrier concentrations signals the onset of exciton–exciton annihilation. The slow component, $\tau_2$, as a function of $n_0$ confirms the presence of exciton–exciton annihilation.

The continuous reduction in $\tau_1$ as a function of $n_0$ in the OA-treated sample implies nontrap limited movement of excitons that are able to annihilate even at low carrier concentrations. At higher excitation intensities the formation of low PLQE trions, as shown in Figure 2b, will contribute to the sharp reduction in $\tau_1$. The TFSI treated sample’s gradual increase in $\tau_1$ at lower initial carrier concentrations is in agreement with the increase in relative PLQE ($\gamma$) in the low intensity (steady-state) excitation regime shown in Figure 2e. At low excitation densities, a proportion of trap states are filled, and any further transition from the band edge to those states is forbidden, which promotes direct recombination from the band edge with $\tau_1$. As carrier concentration increases, trap states are filled giving rise to dominant radiative recombination. The empty orbital provides a binding site for OA as a coordinating group and OA is commonly used as ligands in electron-rich carboxylic acid moiety is a good protonate the monolayer TMD surface and reduce n-doping (this is confirmed by the transistor measurements described below). The electron-rich carboxylic acid moiety is a good coordinating group and OA is commonly used as ligands in stabilizing colloidal quantum dots, providing steric and electronic passivation of surface defects, for example, dangling bonds caused by sulfur vacancies on lead sulfide (PbS) quantum dots. It is therefore reasonable to speculate that the observed improvements in emission could be due to similar passivation, where the carboxylate group behaves as a Lewis base, coordinating to the electrophilic metal (W) atom at the S vacancy forming a dative covalent bond. The W atoms in WS2 possess an unfilled d-orbital due to the energetic gap between the 6s and 5d orbitals. The empty d-orbital does not contribute to covalent bonding and the band structure within monolayer WS2. The empty orbital provides a binding site for OA as a ligand. At vacancy sites, the ligand attachment increases localized electron density and provides mitigation for the nonradiative loss channels at defect sites which are normally
electron-deficient. This increased electron density at these sites may contribute toward the observed additional trion formation at higher excitation intensities. In addition, binding of oleic acid to the monolayer surface provides a hydrophobic long alkyl chain providing a steric and dielectric barrier toward other mechanisms of nonradiative loss mechanisms such as interactions with adsorbates including oxygen and water.

Lastly, we explore what impact the OA treatment has on charge transport in WS$_2$. Figure 4b,c shows the transfer characteristics of the same monolayer WS$_2$ field effect transistor (FET) before and after OA treatment. Raman spectroscopy of the treated transistors confirm there are no discernible structural changes (Figure 4a). After OA treatment the on-state current, measured at back gate voltage $V_G = 25$ V, consistently improves for all of the devices studied (six devices in total) from an average of 11 nA before to 290 nA after (Figure 4b, inset). The device maintains n-type behavior. This confirms that the OA does not significantly dope the monolayer, as is the case for TFSI. The field effect mobility improves from $5 \times 10^{-4}$ cm$^2$/V s to $1 \times 10^{-2}$ cm$^2$/V s, a factor of 20, after OA treatment. The absolute values of field effect mobility are likely limited by contact resistance and could be further improved using recent developments in contact engineering such as van der Waals contacts.49 Importantly, our results show that it is possible to dramatically improve the PL of monolayer WS$_2$ while improving mobility and reducing charge trapping without additional device fabrication steps using OA.

In conclusion, we have demonstrated the ability to significantly increase the PL in monolayer WS$_2$ via surface treatment with OA ligands. Statistical analysis shows that the OA improved spectral uniformity as compared to untreated and TFSI treated samples. Steady-state excitation intensity and time-resolved pump-intensity studies reveal trap free exciton dynamics unlike the trap-limited dynamics observed in TFSI-treated samples,26 which is taken as an indication of defect passivation by the ligands. In support of this hypothesis, electrical transport characteristics of OA treated WS$_2$ transistors show an increase in field effect mobilities, reduced charge trap density, and no detectable additional doping upon treatment with OA. At increased excitation densities, we observe bright trion emission, which is not observed with the TFSI treatment. These bright trions may be of interest for future spintronics and quantum information applications. Although future experimental and theoretical work is required to elucidate the exact chemical changes that accompany the OA treatment, we hypothesize that the carboxylate group forms a dative covalent bond with the electrophilic metal atom (W) at a chalcogen vacancy, similar to the passivation of PbS quantum dots with OA. This trap state passivation by the ligand forbids nonradiative trap-assisted exciton decay, promoting direct radiative band edge recombination. Our results open up a new pathway to passivate and tune defects in monolayer TMDs using simple wet chemistry techniques, allowing for trap free electronic properties and bright neutral exciton and trion emission.

**Experimental Methods. Material Preparation and Initial Characterization.** Prior to exfoliation, substrates were solvent processed via sonication in acetone and isopropyl alcohol (IPA) for ~15 min and treated in O$_2$ plasma to remove adsorbants. Silicon–silicon dioxide (Si–SiO$_2$) substrates with 90 nm oxide layer were used for steady-state PL, Raman spectroscopy, and electronic characterization, whereas quartz substrates were used for steady-state excitation intensity series time-resolved PL measurements.

Large area WS$_2$ monolayers were prepared via gold-mediated exfoliation.50 The bulk crystal purchased from 2D semiconductors was exfoliated manually onto clean-room tape prior to depositing a thin gold layer (~100–150 nm) via thermal evaporation in a thermal evaporator under vacuum conditions. Following gold evaporation, thermal release tape was adhered to the gold-coated WS$_2$ exfoliate, whereupon the cleanroom tape was peeled off, leaving the topmost layer of WS$_2$ attached to the gold on thermal tape. The thermal tape was then stuck onto the freshly plasma-treated target substrate and heated on a hot plate up to 125 °C, whereupon the thermal tape peals leaving the TMD monolayers sandwiched between the gold and substrate. The excess gold was removed by immersing in potassium iodide (KI) and iodine (I$_2$) standard gold etch (Sigma-Aldrich). The substrate was gently swirled in the etchant for 4 min prior to rinsing in deionized water, 10 min sonication in acetone, and 5 min rinse in isopropyl alcohol (IPA). Samples were dried with a nitrogen (N$_2$) gun. Monolayers were initially identified via the optical contrast method.21

**OA Treatment.** In a nitrogen glovebox, the exfoliated monolayer TMD samples were submerged in degassed OA (Sigma-Aldrich) contained in 60 mL vials. The vials were placed on a hot plate set to 25 °C for 12 h overnight after which the samples were rinsed in anhydrous toluene and blow dried with a N$_2$ gun. The OA may also be drop casted. PL spectroscopy reveals that the toluene rinse slightly improves PL as shown in SI Figure 5. This is considered a result of surface cleaning which may remove some adsorbants that quench PL.

**TFSI Preparation and Treatment.** Following Amani et al.,21 2 mg/mL of acid was prepared in a nitrogen glovebox by dissolving 20 mg of TFSI crystals in 10 mL of 1,2-dichloroethane (DCE). Further dilution produced a 0.2 mg/mL solution of acid. The TMD sample was immersed in the acid and tightly closed vial for 40 min at room
After treatment, the sample was removed and dried with a N$_2$ gun.

**Steady-State Absorption Spectroscopy.** The absorption spectra of monolayer WS$_2$ on quartz were measured with a Zeiss axiovert inverted microscope in transmission using a halogen white light source via a Zeiss EC Epiplan Apochromat 50x objective (numerical aperture (NA) = 0.95) forming a collection area diameter measured at 10 $\mu$m with the field of view and aperture fully opened. Light transmitted via the sample was split via beam splitter with one component directed to a CCD camera (DCC3240C, Thorlabs) and the other coupled to a UV600 nm optical fiber (200–800 nm spectral range) connected to a spectrometer (Avaspec HS2048, Avantes).

**Steady-State PL Spectroscopy.** All samples were characterized via steady state PL to confirm monolayer identity before and after treatment. PL spectroscopy was performed on a Renishaw Invia confocal setup equipped with motorized piezo stage, using an air-cooled Ar-ion 514.5 nm continuous wave (CW) laser via 50x objective (NA = 0.75). Signals were collected in reflection via notch filter. The diffraction limited beam spot size was estimated as 0.84 $\mu$m. PL signal was dispersed via a 600 L/mm grating prior to detection with inbuilt CCD detector. Laser power was measured directly via 5x objective with a Thorlabs S130C photodiode and PM100D power meter.

PL maps were generated from multiple WS$_2$ monolayers before and after respective chemical treatments. For the OA treated sample, five monolayers on a single substrate were mapped prior to treatment. Following treatment, two out of five were delaminated, most likely due to surface tension effects exerted by OA. The remaining three treated monolayers were measured in PL and compared to their untreated cases. For TFSI, five untreated monolayers on a single substrate were mapped and remained intact following treatment. Maps were generated with 0.5 $\mu$m resolution and 0.5 s integration time at 0.75 $\mu$W with cosmic ray correction engaged via the microscope’s WIRE software.

Steady-state PL intensity series were performed on the WS$_2$ monolayers deposited on quartz. Care was taken to measure PL in the same locations prior to and following treatment. The spatial $x$, $y$, and $z$ focal plane of the measurement site and photodiode were recorded to accurately switch between photodiode and monolayer location for each PL measurement using the WIRE software piezo stage control interface. PL signals were scaled up to 500 s integration time used on the lowest excitation intensity. Dark counts were measured for each measurement in the series with the same integration time and subtracted from raw PL data.

Trion and neutral exciton emission were deconvoluted from OA treated WS$_2$ PL signals with dark counts subtracted using a procedure written in Matlab, which incorporates the “gauss2” two Gaussian model fit. Further information on the Gaussian model is available via the mathworks Web site.

**Time-Resolved PL Microscopy.** Time-resolved PL measurements were performed on the same samples on quartz prior to and following treatment. A PicoQuant Microtime 200 confocal time-resolved PL setup equipped using 405 nm pulsed laser excitation via 20x objective (NA = 0.4) with estimated diffraction limited spot size of $\sim$1.23 $\mu$m. The repetition rate was set to 20 MHz with 25 ps resolution used to obtain time-resolved PL data. All signals were integrated for 300 s and collected in transmission. Signals were detected with a photomultiplier tube (PMT). Instrument response functions were measured with blank quartz substrates at each power used in the intensity series. Power was measured using an inbuilt photodetector at each intensity and read via the microscope’s software interface. Care was taken to ensure that excitation was performed in the same spot on the monolayers prior to and following treatment. PL decay data were fitted with the aid of an openly available Matlab based deconvolution procedure, fluoFit devised by Jorg Enderlein.$^{25}$ The URL for this code is provided in SI.

**Transistor Preparation and Characterization.** As-exfoliated isolated WS$_2$ flakes on doped Si (used as global back gate) covered with 90 nm of thermally grown SiO$_2$ were identified through optical microscopy and PL spectroscopy. Electrical contacts were defined by electron beam lithography followed by thermal evaporation of indium/gold (In/Au) (10 nm/80 nm). Transfer characteristics were measured with a source drain bias of $V_{DS}$ = 10 V using a Keithley 4200-SCS parameter analyzer and probe station under dark ambient conditions.

**FET Raman Characterization.** Field effect transistors (FETs) were characterized via Raman spectroscopy with the Renishaw Invia confocal setup described, at 0.7 $\mu$W with 50x objective. The Raman signal was collected in reflection via notch filter and dispersed via 2400 L/mm gratings prior to detection.

**TOC Design.** TOC nanocrystal graphics were developed in VESTA software$^{33}$ and parsed into ChemDraw3D (PerkinElmer) for rendering.
