Abstract The cGMP sensitivity of cyclic nucleotide–gated (CNG) channels can be modulated by changes in phosphorylation catalyzed by protein tyrosine kinases (PTKs) and protein tyrosine phosphatases. Previously, we used genistein, a PTK inhibitor, to probe the interaction between PTKs and homomeric channels comprised of α subunits (RETα) of rod photoreceptor CNG channels expressed in Xenopus oocytes. We showed that in addition to inhibiting phosphorylation, genistein triggers a noncatalytic interaction between PTKs and homomeric RETα channels that allosterically inhibits channel gating. Here, we show that native CNG channels from rods, cones, and olfactory receptor neurons also exhibit noncatalytic inhibition induced by genistein, suggesting that in each of these sensory cells, CNG channels are part of a regulatory complex that contains PTKs. Native CNG channels are heteromers, containing β as well as α subunits. To determine the contributions of α and β subunits to genistein inhibition, we compared the effect of genistein on native, homomeric (RETα and OLFα), and heteromeric (RETα+β, OLFα+β, and OLFα+RETβ) CNG channels. We found that genistein only inhibits channels that contain either the RETα or the OLFβ subunits. This finding, along with other observations about the maximal effect of genistein and the Hill coefficient of genistein inhibition, suggests that the RETα and OLFβ subunits contain binding sites for the PTK, whereas RETβ and OLFα subunits do not.

Key words: cyclic guanosine monophosphate • protein tyrosine kinase • photoreceptor • olfactory receptor neuron

Introduction Cyclic nucleotide–gated (CNG)1 channels are crucial for sensory transduction in rod and cone photoreceptors and olfactory sensory neurons. The cyclic nucleotide sensitivity of CNG channels can be modulated by various intracellular signals including Ca2+/calmodulin (Chen et al., 1994; Grunwald et al., 1998) and phosphorylation (Gordon et al., 1992; Molokanova et al., 1997, 1998). We recently showed that the cyclic GMP sensitivity of CNG channels expressed in Xenopus oocytes, consisting of homomers of bovine rod α subunits (RETα) can be modulated by protein tyrosine kinases (PTKs) and phosphatases (PTPs) intrinsic to the oocyte (Molokanova et al., 1997, 1999b). These enzymes are constitutively active and remain associated with inside-out membrane patches for many minutes after excision, consistent with a relatively stable multimeric complex including CNG channels, PTKs, and PTPs. Similar complexes between ion channels, protein kinases, and protein phosphatases have been shown for several other channels (Levitan, 1999) and may be the rule rather than the exception.

We have probed the interaction between the rod CNG channel and the oocyte PTK using the tyrosine kinase inhibitor genistein (Molokanova et al., 1999a). In addition to preventing PTK-catalyzed changes in cGMP sensitivity when ATP is present, genistein also inhibits channel gating in the absence of ATP. Thus, genistein can inhibit CNG channels even when the PTK is catalytically inactive. The simplest possible explanation would involve direct binding of genistein to the channel. However, genistein inhibition can be suppressed by agents that have no direct effect on CNG channels, but that do inhibit PTKs. Erbstatin, a noncompetitive inhibitor of the ATP binding site on PTKs (Imoto et al., 1987), noncompetitively prevents genistein inhibition. Adenylylimidodiphosphate (AMP-PNP), a nonhydrolyzable ATP analogue that competitively inhibits PTKs (Akiyama et al., 1987), competitively inhibits genistein inhibition. These results and other observations lead to the conclusion that genistein indirectly influences RETα channels by triggering a noncatalytic interaction between oocyte PTKs and the channel that allosterically inhibits channel gating.

Are native CNG channels in sensory cells, like CNG channels expressed in oocytes, associated with PTKs? Our recent work shows that CNG channels in rod outer segments are subject to modulation by changes in ty-
rosine phosphorylation, the final step in a biochemical cascade in which neuromodulators can alter the rod light response (Savchenko, Kraft, Molokanova, Kramer, manuscript in preparation). Since genistein has been useful in probing the interaction between the cloned RET<sub>a</sub> channel and oocyte PTKs, we asked whether genistein would reveal a similar interaction between native CNG channels and PTKs in sensory cells, namely rods, cones, and olfactory receptor neurons.

Both the native rod and olfactory CNG channels are heteromers containing α and β subunits (Bradley et al., 1994; Chen et al., 1994, Liman and Buck, 1994; Koerschen et al., 1995), named RET<sub>a</sub> and RET<sub>b</sub> in rods and OL<sub>a</sub> and OL<sub>b</sub> in olfactory neurons. Exogenous expression of α subunits alone generates functional CNG channels in oocytes. In contrast, β subunits do not form functional channels when expressed alone. However, coexpression of α and β subunits yields channels with properties that more closely resemble native rod and olfactory channels. To better understand how α and β subunits of CNG channels interact with PTKs, we compared the effects of genistein on native, cloned homomeric, and cloned heteromeric channels. Our results suggest that all three native CNG channels (rod, cone, and olfactory) are indeed associated with PTKs. However, for the rod channel, the α subunit is crucial for allowing interaction with the PTK, whereas in the olfactory CNG channel, the β subunit is crucial.

Materials and Methods

Recording from Native CNG Channels

Water-phase tiger salamanders (Ambystoma tigrinum) maintained in a temperature-controlled aquarium (4°C) on a 12/12 light/dark cycle were used in experiments at the same time of day. Animals were dark-adapted for 1 h and anesthetized in an ice-cold solution containing 1 g/liter of 2-amino benzoic acid for 20 min before decapsulation and removal of eyes under dim red light. Eyes were placed in physiological saline containing (mM): 155 NaCl, 2.5 KCl, 1 CaCl<sub>2</sub>, 2 MgCl<sub>2</sub>, 10 glucose, and 10 HEPES, pH 7.5. Retinas were removed and gently triturated to yield isolated rods, cones, or rod outer segments. Borosilicate glass pipettes (3–5 MΩ) were filled with standard patch solution containing (mM): 115 NaCl, 5 EGTA, 1 EDTA, and 10 HEPES, pH 7.5 with NaOH, and were used to obtain excised inside-out patches from outer segments of rods and cones.

Olfactory receptor neurons were acutely dissociated from the epithelium was placed for 18–22 min at 21°C in a tube containing 3 ml of physiological solution (mM): 148 NaCl, 4 KCl, 1.5 CaCl<sub>2</sub>, 2 MgCl<sub>2</sub>, 10 glucose, 10 HEPES, pH 7.4 containing 48 μM of cytostatin-cactivated papain (Worthington Pharmaceuticals). The tissue was then continuously washed for 10 min in ice-cold papain-free solution and gently triturated to isolate individual olfactory receptor neurons. Patch pipettes with resistances of 10–20 MΩ were used for obtaining excised patches. Pipettes were filled with a solution containing (mM): 150 NaCl, 4 KCl, 5 EGTA, 0.2 MgCl<sub>2</sub>, 10 glucose, 10 HEPES, pH 7.4. This also served as the bath solution and cGMP perfusion solution for experiments on olfactory neurons.

Expression and Recording from CNG Channels Expressed in Xenopus Oocytes

To generate homomeric channels, a cDNA clone encoding the α subunits of the bovine rod photoreceptor CNG channel (Kaupp et al., 1989) or the rat olfactory CNG channels (Dhallan et al., 1992) were used for in vitro transcription of mRNA, which was injected into Xenopus oocytes (50 nI per oocyte at 1 ng/nI). After 2–7 d, the vitelline membrane was removed from injected oocytes, which were then placed in a chamber for patch-clamp recording at 21–24°C. Glass-patch pipettes (2–3 MΩ) were filled with standard patch solution, which also served as the standard bath solution and cGMP perfusion solution. After formation of a gigaohm seal, inside-out patches were excised and the patch pipette was quickly (<30 s) placed in the outlet of a 1-mm diameter tube for application of cGMP and other agents. We used a perfusion manifold containing up to eight different solutions capable of solution changes within 50 ms. Most patches contained 100–200 channels.

To generate heteromeric RET<sub>a</sub> + RET<sub>b</sub> channels, mRNA encoding RET<sub>a</sub> and RET<sub>b</sub> (Koerschen et al., 1995) were coinjected into oocytes. The presence of heteromers in excised patches was confirmed by application of saturating (2 mM) cGMP in conjunction with 10 μM l-cis diltiazem, which selectively blocks channels containing β subunits, but is ineffective at blocking homomeric RET<sub>a</sub> channels (Chen et al., 1993). Injection of a 1:8 (n = 6) or 1:10 (n = 14) ratio of RET<sub>a</sub> to RET<sub>b</sub> mRNA produced channels that were inhibited 78 and 80%, respectively, by 10 μM l-cis diltiazem. In contrast, a 1:5 ratio generated channels inhibited by 50%, suggesting that a RET<sub>a</sub>:RET<sub>b</sub> mRNA ratio of 1:10 is sufficient to saturate the RET<sub>b</sub> contribution to heteromeric channels, consistent with previous results (Shammat and Gordon, 1999). For expression of OL<sub>a</sub> + OL<sub>b</sub> heteromeric channels, OL<sub>a</sub> and OL<sub>b</sub> (Liman and Buck, 1994) mRNAs were injected at a ratio of 4:1, previously reported to saturate the contribution of OL<sub>b</sub> to olfactory heteromeric channels (Shapiro and Zagotta, 1998). In agreement with these earlier results, we found that injection of this ratio of mRNAs generated channels with increased sensitivity to cAMP as compared with homomeric OL<sub>a</sub> channels (K<sub>V</sub>) of 9.5 ± 0.8 μM (n = 11) and 130 ± 9 μM (n = 12), respectively.

For expression of hybrid OL<sub>a</sub>–RET<sub>b</sub> channels, mRNAs encoding the two subunits were co-injected into oocytes. The presence of RET<sub>b</sub> in hybrid channels was confirmed by applying 10 μM l-cis diltiazem (Finn et al., 1998). This inhibitor blocked channels resulting from OL<sub>a</sub> to RET<sub>b</sub> mRNA injection ratios of 1:1.5 and 1:3 by 36.8 ± 2.9% (n = 3) and 32.8 ± 1.4% (n = 6), respectively. These results suggest that a OL<sub>a</sub> to RET<sub>b</sub> injection ratio of 1:3 is sufficient to saturate the contribution of RET<sub>b</sub> to hybrid channels.

Analysis of Genistein Inhibition

Genistein and erbstatin (stable analogue) were purchased from Alexis Corp. and were prepared as concentrated stock solutions in DMSO. Aqueous solutions containing the final concentrations were prepared for use as needed. The final concentration of DMSO did not exceed 0.1%, which had no effect on CNG channels or their modulation. Cyclic GMP and AMP-PNP were purchased from Sigma Chemical Co. Current responses through CNG channels were obtained with an Axopatch 200A patch clamp (Axon Instruments, Inc.), digitized, stored, and later analyzed using pClamp 6.0 software. Membrane potential was held at −75 mV in all experiments. Current responses were normalized to the maximal CNG current (I<sub>max</sub>), elicited by saturating (2 mM) cGMP. To estimate the K<sub>i</sub> for genistein, we used a modified Hill equation: I<sub>y</sub>/I<sub>max</sub> = [(1 – I<sub>max</sub>/I<sub>max</sub>)]/(1 + (K<sub>i</sub>/B)<sup>y</sup>) where...
$I_{b_{(m)}} / I_{m}$, where B is the concentration of blocker, $I_b$ and $I_{b_{(m)}}$ are the currents activated by saturating cGMP in the presence of a given blocker concentration, and a saturating blocker concentration, respectively. Genistein inhibition of closed and fully activated channels was analyzed as described previously (Molokanova et al., 1999a). Variability among measurements is expressed as mean ± SEM.

RESULTS

Genistein Inhibition of Native CNG Channels

Application of genistein on expressed homomeric rod channels (RETα) stabilizes the closed state of the channel, such that preapplication of genistein slows activation upon exposure to cGMP (Molokanova et al., 1999a). Fig. 1 shows that genistein has a similar effect on native channels in patches excised from salamander rod outer segments. Without genistein, saturating cGMP (2 mM) rapidly activates CNG current (Fig. 1 A). However, if the channels are pretreated with genistein (Fig. 1 B), a fraction of the CNG current activates very slowly ($\tau = 8.5 \text{s}$), while the residual current activates over the normal rapid time course ($\tau = 20 \text{ms}$). By examining these two components with different concentrations of genistein, we previously showed that the slowly activating current reflects channels inhibited by genistein, whereas the residual current reflects channels that are unaffected by genistein. Genistein also inhibits channels after they have been maximally activated by saturating cGMP (Fig. 1 C), but the extent of inhibition is less than for closed channels. Hence, genistein more effectively inhibits closed than open rod channels, as was observed previously for the expressed RETα channel.

Genistein inhibition of the expressed RETα channel is suppressed by coapplication of PTK inhibitors that have no direct effects on CNG channels (Molokanova et al., 1999a). These include AMP-PNP, a nonhydrolyzable ATP analogue that competes with genistein for the ATP binding site on PTKs, and erbstatin, a noncompetitive inhibitor of PTKs with respect to genistein. Fig. 2 shows that both AMP-PNP and erbstatin also reduce genistein inhibition of the native rod channels. Thus, genistein inhibition of both closed (Fig. 2 A) and fully activated (B) native rod CNG channels is markedly reduced by coapplication of AMP-PNP or erbstatin. AMP-PNP and erbstatin have no effect on the kinetics, cGMP sensitivity, or maximal current in the absence of genistein ($n = 4$). The observation that genistein inhibition is suppressed by two known PTK inhibitors that have no direct effect on the rod channel strongly suggests that, as in oocytes, genistein inhibits the native rod channel indirectly, by first binding to a PTK.

Native CNG channels differ in their sensitivity to genistein inhibition (Fig. 3). Genistein has a much larger effect on CNG channels from rods and cones than on channels from olfactory receptor neurons. Maximal inhibition of closed channels by saturating concentrations of genistein (500 μM) was 61 ± 8% ($n = 9$) for rod, 50 ± 3% ($n = 8$) for cone, and 28 ± 4% ($n = 5$) for olfactory channels (Fig. 3 A). As observed in homomeric RETα channels, genistein was less effective at inhibiting fully activated channels (Fig. 3 B) [inhibition of 31 ± 4% ($n = 5$) for rod, 37 ± 3% ($n = 4$) for cone, and 11 ± 4% ($n = 3$) for olfactory channels]. Moreover, for rod and cone CNG channels, fully activated channels had a higher apparent $K_i$ for genistein than did closed channels (Fig. 3 C), again consistent with previ-
ous observations. For olfactory CNG channels, $K_i$ values for genistein inhibition of closed and open channels were not significantly different. Not only did genistein have a smaller maximal effect on olfactory channels, but the apparent $K_i$ for genistein was also higher than values for channels from rods or cones (Fig. 3 C).

**Role of RET$\alpha$ and RET$\beta$ Subunits in Genistein Inhibition of Rod CNG Channels**

While inhibition of native rod channels is qualitatively similar to that of expressed homomeric RET$\alpha$ channels, there are striking quantitative differences. Thus, saturating genistein can completely suppress activation of closed RET$\alpha$ channels (inhibition of 98 ± 5% (n = 20), whereas activation of native channels is maximally reduced by only 61 ± 8% (n = 9). Fig. 4 shows that the RET$\beta$ subunit almost entirely accounts for this difference. Thus, heteromeric RET$\alpha$+β channels behave in a manner very similar to native rod channels, with channels in their closed state exhibiting a maximal genistein inhibition of 53 ± 5% (n = 10) (Fig. 4 A).

Moreover, the apparent $K_i$ of heteromeric RET$\alpha$+β channels was 20 μM, a value much higher than for homomeric RET$\alpha$ channels (4 μM), but similar to that for native rod channels (19 μM) (Fig. 4 B). The Hill coefficient also differs for native rod CNG channels (~1) and homomeric RET$\alpha$ channels (~2), but the value for heteromeric RET$\alpha$+β channels (~2) is indistinguishable from that for native channels.

The same is true of rod channels in their open state. Genistein inhibition of native rod channels more closely resembles inhibition of heteromeric RET$\alpha$+β than of homomeric RET$\alpha$ channels (Fig. 5 A). In the presence of saturating cGMP (2 mM), genistein inhibits native, homomeric RET$\alpha$, and heteromeric RET$\alpha$+β channels by 31 ± 4% (n = 5), 67 ± 4% (n = 18), and 37 ± 3% (n = 9), respectively. Fig. 5 B shows that $K_i$ values for genistein on fully activated channels was ~51 μM for native, 82 μM for RET$\alpha$, and 53 μM for RET$\alpha$+β. The Hill coefficient was similar for inhibition of each of the open channels, with values near 1 for each. However, while the Hill coefficients for inhibi-
tion of native and heteromeric RETαβ are the same for open and closed channels (~1 for each), for homomeric RETα channels, the Hill coefficient changes from 2 when the channels are closed to 1 when the channels are fully activated.

The β subunit also accounts for differences in the kinetics of genistein inhibition. Genistein inhibition of open native rod channels is relatively fast, with a time constant of 1.2 s for fully activated channels (see Fig. 1 C). In contrast, the time course of genistein inhibition of open homomeric RETα channels is much slower (Fig. 6 A), with a time constant of 9 s. The kinetics of inhibition of heteromeric RETαβ channels (Fig. 6 B) are similar to that of native channels with a time constant of ~1 s. The kinetics of genistein inhibition are similar at a range of genistein concentrations from 25 to 1,000 µM. This suggests that the rate-limiting step in inhibition is not genistein binding, but rather the interaction between the PTK and channel subunits.

Role of OLFα and OLFβ Subunits in Genistein Inhibition of Olfactory CNG Channels

Like rod CNG channels, native olfactory CNG channels are heteromers containing OLFα and OLFβ subunits, in addition to a splice variant of the RETβ subunit (Sautter et al., 1998; Bonigk et al., 1999). To determine whether OLFα, like RETα, is the primary target for genistein inhibition, we examined the effect of genistein on homomeric OLFα channels. Fig. 7 shows that genistein fails to inhibit both closed (A) and fully activated (B) OLFα channels, at concentrations up to 500 µM (n = 4). In contrast, heteromeric channels, formed by coexpressing
Figure 4. Subunit dependence of genistein inhibition of closed rod CNG channels. (A) Dose-inhibition curves for genistein effect on closed native rod, homomeric RETα, and heteromeric RETα+β channels. (B) Bar graph showing $K_i$ and Hill coefficient values for genistein inhibition curves. Data represents mean ± SEM for all individual experiments included in A.

Figure 5. Subunit dependence of genistein inhibition of fully activated rod CNG channels. (A) Dose-inhibition curves for genistein effect on native and homomeric RETα, and heteromeric RETα+β channels. All channels were fully activated with saturating (2 mM) cGMP before genistein application. (B) Bar graph showing $K_i$ and Hill coefficient values for genistein inhibition curves. Data represents mean ± SEM for all individual experiments included in A.
Figure 6. Kinetics of inhibition of fully activated homomeric RETα (A) and heteromeric RETα+β (B) channels by various concentrations of genistein.

Figure 7. Subunit dependence of genistein inhibition of olfactory CNG channels. Dose-inhibition curves for genistein effect on closed (A) and fully activated (B) native (n = 3–5), homomeric OLFα (n = 4), and heteromeric OLFα+β (n = 6) channels.
OLFα and OLFβ subunits were inhibited to an even greater extent than were native olfactory channels.

Studies on hybrid RET + OLF channels

The observation that OLFβ is necessary for genistein inhibition suggests that the PTK responsible for indirectly conferring genistein sensitivity can selectively associate with OLFβ, rather than with OLFα subunits. Do the two RET subunits, RETα and RETβ, also differ in their ability to interact with the PTK and confer genistein inhibition? To address this question, we took advantage of the observation that OLFα is apparently unable to interact with the PTK. If RETβ can interact with the PTK, one might expect that hybrid heteromeric channels (OLFα + RETβ) generated by coexpressing OLFα with RETβ would be subject to genistein inhibition. Expression of such hybrid channels was confirmed by examining their sensitivity to L-cis-diltiazem, which has a heightened affinity for blocking channels that contain the RETβ subunit. Fig. 8 shows that genistein has no effect on these hybrid channels, strongly suggesting that the RETβ subunit does not bind to the PTK responsible for genistein inhibition. Hence we propose that genistein inhibition of rod CNG channels is mediated selectively by the interaction between the PTK and the RETα subunit.

**DISCUSSION**

Multimolecular Complexes between CNG Channels and PTKs

There is a growing realization that ion channels do not exist in isolation, but rather coexist with other proteins in macromolecular complexes. Protein partners of ion channels include cytoskeletal components, anchored via PDZ and other domains (Sheng and Wyszynski, 1997) and regulatory enzymes, such as protein kinases and phosphatases (Levitan, 1999). Biochemical evidence for such regulatory complexes includes copurification or coimmunoprecipitation of various kinases and phosphatases, including PTKs and PTPs, with ion channels (Rehm et al. 1989; Holmes et al., 1996; Yu et al., 1997; Tsai et al., 1999). Electrophysiological evidence for regulatory complexes comes from the ability of ATP to modulate channel gating after isolation from the cytoplasmic environment, either by excising membrane patches or by reconstituting the channels in artificial lipid bilayers. Moreover, modulation can be prevented by application of specific inhibitors of kinases and/or phosphatases (Biefeld and Jackson, 1994; Reinhardt and Levitan, 1995; Molokanova et al., 1997; Wilson et al., 1998). These studies suggest that channels, kinases, and phosphatases are often involved in an intimate, rather than just a casual relationship.

![Figure 8](https://example.com/figure8.png) Figure 8. Summary data for genistein inhibition of various expressed homomeric and heteromeric channels in closed (A) and fully activated (B) states. n = 5–8 for each channel type.
Our studies strongly suggest that CNG channels are part of a regulatory complex that contains PTKs and PTPs. The cGMP sensitivity of homomeric RET\(\alpha\) channels expressed in Xenopus oocytes increases after patch excision, owing to tyrosine dephosphorylation by PTPs (Molokanova et al., 1997). Conversely, application of ATP decreases cGMP sensitivity, owing to tyrosine phosphorylation by PTKs. The observation that modulation can be elicited repeatedly without decrement, even many minutes after patch excision and superfusion, suggests that the PTKs and PTPs responsible for modulation are tightly associated with RET\(\alpha\) channels.

Application of PTP and PTK inhibitors to intact rods shows that the sensitivity of native rod CNG channels is also modulated by changes in tyrosine phosphorylation (Molokanova et al., 1997). However, we have found that in the absence of Ca\(^{2+}\), CNG channels in excised patches from rod outer segments do not exhibit spontaneous changes in cGMP sensitivity and are unaffected by ATP application. In recent studies, we find that extrinsic growth factors, such as IGF-1, can trigger changes in cGMP sensitivity by initiating a cascade that ultimately activates PTPs in rods (Savchenko, Kraft, Molokanova, Kramer, manuscript in preparation). Hence it has been unclear whether the native rod CNG channels are tightly, or only loosely, associated with PTKs and PTPs.

We have used the PTK inhibitor genistein to probe the interaction between PTKs and CNG channels. In previous studies (Molokanova et al., 1999a), we showed that genistein inhibits gating of expressed RET\(\alpha\) channels even in the absence of ATP, indicating that the inhibition does not require catalytic activity of PTKs. However, the genistein effect was suppressed by PTK inhibitors that do not directly interact with CNG channels (AMP-PNP and erbstatin), strongly suggesting that genistein does not directly bind to the channel, but rather affects channel gating indirectly by binding to a PTK. From these studies, we concluded that the PTK can allosterically influence channel gating even without catalyzing phosphorylation. In this paper, we find characteristics of genistein inhibition of native rod CNG channels that are entirely consistent with our previous results on expressed channels, supporting the notion that a similar macromolecular complex, including at least CNG channels and a PTK, must exist in rod outer segments. Since we observe at least some degree of genistein inhibition not only in rods, but also in cones and olfactory neurons, CNG channels in all of these sensory cells may occur in macromolecular complexes with PTKs. The placement of regulatory enzymes, such as PTKs and PTPs, in close apposition with substrate proteins, such as CNG channels, may be important for efficient and rapid signaling. We suggest that, in rods, a complex of CNG channels, PTKs, and perhaps PTPs may be part of a larger “transducosome,” also containing other proteins involved in phototransduction (Koerschen et al., 1999).

Role of \(\alpha\) and \(\beta\) Subunits in Genistein Inhibition

Since homomeric RET\(\alpha\) channels are strongly inhibited by genistein, it appears that the RET\(\alpha\) subunit alone is sufficient for binding the PTK. For heteromeric RET\(\alpha + \beta\) channels, genistein has a lower apparent affinity, smaller maximal effect, and a smaller Hill coefficient for inhibition of closed channels. These observations are consistent with the possibility that genistein inhibition of RET\(\alpha + \beta\) channels is solely mediated by interaction between the PTK and the RET\(\alpha\) subunit, with the RET\(\beta\) subunit unable to bind. However, it also possible that the PTK binds to both subunits, but in the context of the heteromeric RET\(\alpha + \beta\) channel, binding of the PTK to each subunit is less favorable. The observation that genistein has no effect on hybrid OLF\(\alpha\) + RET\(\beta\) channels helps distinguish between these possibilities. Thus, the RET\(\beta\) subunit is unable to confer genistein sensitivity when coexpressed with OLF\(\alpha\) subunits, which by itself is insensitive. The OLF\(\beta\) subunit does confer genistein sensitivity when coexpressed with OLF\(\alpha\), indicating that OLF\(\alpha\) is not simply “dominant negative” for genistein inhibition. Hence, we conclude that genistein inhibition of rod channels is exclusively mediated by an interaction between the PTK and the RET\(\alpha\) subunit. The RET\(\beta\) subunit does appear to alter the kinetics of this interaction (Fig. 6), perhaps through an allosteric influence on RET\(\alpha\) subunits.

The situation is different for olfactory CNG channels. Homomeric OLF\(\alpha\) channels are unaffected by genistein, whereas heteromeric OLF\(\alpha + \beta\) channels are inhibited, suggesting that the OLF\(\beta\) subunit, rather than the OLF\(\alpha\), interacts with the PTK. Hence, whereas the \(\alpha\) subunit interacts with the PTK in rod CNG channels, the \(\beta\) subunit interacts with the PTK in olfactory CNG channels. It should be noted that the nomenclature of CNG channel subunits (\(\alpha\) vs. \(\beta\)) is not based on sequence homology, but rather is based on the chronology of subunit cloning, such that the first cloned subunits were named “\(\alpha\)” and the second named “\(\beta\).” In fact, the two subunits that are unable to interact with the PTK (OLF\(\alpha\) and RET\(\beta\)) share a homologous domain in the NH\(_2\) terminus that enables these subunits to interact with Ca\(^{2+}\)/calmodulin (Chen et al., 1994; Liu et al., 1994). It remains to be determined whether this region somehow inhibits PTK binding to these subunits, rendering them genistein insensitive. It also remains to be determined whether the RET\(\alpha\) and OLF\(\beta\) subunits share regions that allow interaction with the PTK, enabling genistein inhibition. In addition, it should be noted that native olfactory CNG channels appear to contain not only OLF\(\alpha\) and OLF\(\beta\) subunits, but
also a splice variant of the RETβ subunit (Sautter et al., 1998; Bonigk et al., 1999). In our expressed heteromeric OLFα+β channels (Fig. 8), the lack of RETβ subunit, which apparently does not bind PTK, may account for the greater degree of genistein inhibition as compared with native olfactory channels.

Stoichiometry of Interactions between PTKs and CNG Channel Subunits

Fig. 9 A presents one possible mechanism for how PTKs might interact with the subunits of CNG channels. The Hill coefficient for genistein inhibition of closed homomeric RETα channels is 2. If this accurately reflects the number of genistein binding sites, it would suggest that two PTKs are involved in channel inhibition. Since the homomeric channel contains four identical subunits, it is possible that each PTK simultaneously interacts with two neighboring subunits (Fig. 9 A, left). Many receptor-type PTKs, such as growth factor receptors, either contain repeating domains or are dimeric proteins (Fantl et al., 1993), providing a possible structural basis for PTK binding to identical sites on adjacent channel subunits. However, it is possible that the Hill coefficient underestimates the number of genistein binding sites. Thus, more than two PTKs (e.g., four PTKs) may underlie genistein inhibition, with each subunit individually inhibited by its own enzyme. To illustrate the uncertainty in the number of PTKs involved (two or four), the illustrated PTKs are divided in half with a dotted line.

What accounts for the curious decrease in the value of the Hill coefficient from two to one as RETα channels go from closed to open during activation? Recent studies suggest that rather than acting independently or in a completely concerted manner, the four subunits of some CNG channels may function as a pair of independent dimers. Thus, for each functional dimer, the two participating channel subunits cooperatively bind cyclic nucleotide and activate in a concerted manner (Liu et al., 1998; Shammat and Gordon, 1999). We propose that functional dimerization of RETα subunits is dependent on binding of cyclic nucleotide. Hence, whereas all the RETα subunits are equivalent when the channel is closed, cGMP binding and/or channel opening triggers association of adjacent channel subunits, allowing them to function as a dimer. The minimal number of genistein molecules required to inhibit a channel containing such a pair of functional dimers is 1. This assumes that the PTK preferentially interacts "perpendicularly" with respect to the functional dimers; that is, by binding to RETα subunits on two distinct functional dimers (Fig. 9 A, right). Since the PTK can bind to the channels in their closed state, binding of the PTK to two adjacent RETα subunits may actually determine which RETα subunits functionally dimerize, namely the RETα subunits that are not already joined by a PTK. In this scenario, PTK-dependent subunit linkage between subunits and cGMP-dependent functional dimerization are mutually exclusive.

In the heteromeric RETα+β channel (Fig. 9 B), only the RETα subunits are capable of binding the PTK. Hence, if the channel stoichiometry is indeed RETα2, RETβ2, a single PTK dimer could interact with adjacent RETα subunits, fully accounting for genistein inhibition because the RETβ subunits appear to be immune...
to genistein inhibition. This scenario is consistent with our observed Hill coefficient for genistein inhibition of 1, and also accounts for the reduced maximal effect of genistein. Moreover, the proposed subunit arrangement is supported by recent studies by Shammat and Gordon (1999), who established that α subunits in heteromeric RET channels are adjacent rather than diagonally opposed.

The role of α and β subunits with respect to genistein inhibition is reversed in the OLF channel. Homomeric OLFα channels are unaffected by genistein, suggesting that the OLFα subunit cannot interact with the PTK (Fig. 9 C). However, the OLFβ subunit confers genistein sensitivity, suggesting that OLFβ subunits contain a PTK binding site. The Hill coefficient of heteromeric OLFα+β channels is one for both closed and fully activated channels, consistent with PTK spanning two functional dimers via interaction with two adjacent β subunits (Fig. 9 D).

These diagrams are speculative and are only a starting point for considering the stoichiometric relationships between PTKs and subunits of CNG channels. Estimates of stoichiometries based on Hill coefficients need to be confirmed with more direct biochemical experiments. Various factors, including heterogeneous populations of channels (Ruiz et al., 1999) and positive cooperativity between channel subunits (Fig. 9 D).
