Evidence for a Hydrogenosomal-Type Anaerobic ATP Generation Pathway in *Acanthamoeba castellanii*

Michelle M. Leger*, Ryan M. R. Gawryluk*, Michael W. Gray, Andrew J. Roger*

Department of Biochemistry and Molecular Biology, Centre for Comparative Genomics and Evolutionary Bioinformatics, Dalhousie University, Halifax, Nova Scotia, Canada

Abstract

Diverse, distantly-related eukaryotic lineages have adapted to low-oxygen environments, and possess mitochondrion-related organelles (MROs), which, although derived from mitochondria, have lost the capacity to generate adenosine triphosphate (ATP) through oxidative phosphorylation. A subset of these organelles, hydrogenosomes, have acquired a set of characteristic ATP generation enzymes commonly found in anaerobic bacteria. The recipient of these enzymes could not have survived prior to their acquisition had it not still possessed the electron transport chain present in the ancestral mitochondrion. In the divergence of modern hydrogenosomes from mitochondria, a transitional organelle must therefore have existed that possessed both an electron transport chain and an anaerobic ATP generation pathway. Here, we report a modern analog of this organelle in the habitually aerobic opportunistic pathogen, *Acanthamoeba castellanii*. This organism possesses a complete set of enzymes comprising a hydrogenosome-like ATP generation pathway, each of which is predicted to be targeted to mitochondria. We have experimentally confirmed the mitochondrial localizations of key components of this pathway using tandem mass spectrometry. This evidence is the first supported by localization and proteome data of a mitochondrion possessing both an electron transport chain and hydrogenosome-like energy metabolism enzymes. Our work provides insights into the first steps that might have occurred in the course of the emergence of modern hydrogenosomes.

Introduction

The capacity to produce adenosine triphosphate (ATP) under low oxygen conditions is found throughout the eukaryote tree, in diverse, distantly-related organisms. Of the lineages of this type that have been studied, most are anaerobic or microaerobic, and possess mitochondrion-related organelles (MROs), which, although derived from mitochondria, have lost the capacity to generate ATP through oxidative phosphorylation (reviewed in [1]). Some of these organelles, known as hydrogenosomes, have adopted a new function in anaerobic ATP generation by acquiring a set of characteristic enzymes that are commonly found in anaerobic bacteria [2–4]. In other anaerobic/microaerobic eukaryotes with more highly reduced MROs, such as anaerobic bacteria [2–4], in other anaerobic/microaerobic eukaryotes with more highly reduced MROs, such as *Giardia intestinalis* and *Entamoeba histolytica*, homologous enzymes are localized in the cytosol, and the MROs of these organisms are not involved in ATP generation [5,6]. MROs have long been classified according to their role in energy metabolism, and a recent review [7] retains the categories of mitochondria (class 1 under the authors’ classification system), hydrogenosomes (class 4) and mitosomes (class 5), while proposing new classes to formally accommodate the more diverse range of MROs now known: anaerobically functioning mitochondria that do not produce hydrogen (class 2) and mitochondria that both possess an electron transport chain and produce hydrogen (class 3).

The best-characterized hydrogenosomes are those of the obligately parasitic parabasalid *Trichomonas vaginalis*. In mitochondria, the first step of pyruvate catabolism involves the decarboxylation of pyruvate by the enzyme complex pyruvate dehydrogenase (PDH, EC 1.2.1.51), which produces acetyl-CoA and CO₂ with the concomitant reduction of NAD⁺ to NADH. In the hydrogenosomes of *T. vaginalis*, pyruvate decarboxylation is instead carried out by pyruvate:ferredoxin oxidoreductase (PFO, EC 1.2.7.1) [8,9]. In other eukaryotes such as *Cryptostomum purpureum*, *Neocallimastix frontalis* or *Mastigamoeba halani*, a similar function is performed by a pyruvate:NAD oxidoreductase (PNO, EC 1.2.1.11) or pyruvate:ferredoxin oxidoreductase (PFL, EC 2.3.1.54) [12,13]. Electrons produced during pyruvate decarboxylation by PFO are transferred first to a [2Fe-2S] ferredoxin, and then to [FeFe]-hydrogenase (EC 1.12.1.4), which reduces protons, producing molecular hydrogen. Three maturases, HydE, HydF and HydG, are involved in the assembly and insertion of the catalytic iron-sulfur clusters in bacterial [FeFe]-hydrogenases, and homologs of these enzymes have been reported in some, though not all,
eukaryotes possessing this enzyme [14–16]. Coenzyme A is transferred from the resulting acetyl-CoA to succinate by an acetyl-CoA:succinate CoA transferase (ASCT, EC 2.8.3.9) [17], generating acetyl-CoA and succinyl-CoA. The subsequent regeneration of succinate, catalyzed by the tricarboxylic acid (TCA) cycle enzyme succinate thiokinase (STK, also referred to as succinyl-CoA synthetase, EC 6.2.1.4), generates ATP through substrate-level phosphorylation [4]. ASCTs found in eukaryotes have been classified into three subfamilies [17]. Enzymes of subfamily 1A, found in the mitochondria of trypanosomatids [18] and in the hydrogenosomes of rumen ciliates [19], are homologous to the succinyl-CoA:3-oxoadipate CoA transferases (SCOT) that are involved in ketone body degradation in metazoan mitochondria. Members of subfamily 1B have been reported in the mitochondria of acetate-producing metazoans such as Fasciola hepatica [20] and Artemia franciscana [21]. Based on in silico predictions, they are also believed to be present in Blastocystis sp. [17] and in the mitochondria of Naegleria gruberi [22]. Enzymes of subfamily 1C have been found in the hydrogenosomes of T. vaginalis [23], Blastocystis sp. [24,25], and the chytrid fungus Neocallimastix [17,26,27].

Until recently, the only aerobic eukaryotes known to possess both [FeFe]-hydrogenase and PFO were green algae such as Chlamydomonas reinhardtii [24,25], and the chytrid fungus Neocallimastix [22]. In 2010, genes encoding an [FeFe]-hydrogenase and PFO were expressed upon exposure to anoxic conditions, and localize to the chloroplast, where they function in both anaerobic energy production and anaerobic photosynthesis [27–29]. In 2010, genes encoding an [FeFe]-hydrogenase and the three [FeFe]-hydrogenase maturases were identified in the genome of Naegleria gruberi, an aerobic heterolobosean; in silico predictions suggested that these enzymes might be mitochondrially targeted [22]. No PFO homologs have been found in the genome of this organism.

Previous studies have attempted to clarify the origin of these enzymes in eukaryotes; these efforts have generally been hampered by the small number of eukaryotic sequences available, and by low resolution in all parts of the tree. Phylogenetic analyses of [FeFe]-hydrogenase sequences have consistently recovered more than one eukaryotic clade, suggesting at least two origins of these enzymes in eukaryotes [16,30–33]. A specific relationship between eukaryotic [FeFe]-hydrogenases and their homologs in α-proteobacteria has been rejected in topology tests, providing evidence against a mitochondrial endosymbiotic origin of [FeFe]-hydrogenases in extant eukaryotes [16]. Analyses of [FeFe]-hydrogenase maturases recovered robust eukaryotic clades in all cases; however, the internal relationships within these clades were poorly supported and their closest prokaryotic homologs were, in no case, α-proteobacterial. Similar results were obtained by phylogenetic analyses of PFO [16,34–36]. A neighbor-net analysis of ASCT1B and ASCT1C sequences [23] recovered eukaryote monophyly for both enzymes, consisting of metazoa in the case of ASCT1B, and fungi and T. vaginalis in the case of ASCT1C; at that time these taxa were the only eukaryotes known to possess ASCTs. Again, no clear α-proteobacterial affinity for eukaryotic groups was recovered, and thus there is no clear connection to mitochondrial origins. These observations suggest that lateral gene transfer has played a role in the appearance of these enzymes within eukaryotes; however the number of events involved, and the precise nature of the donor and recipient lineages, remain unclear. Acanthamoeba castellanii is a free-living soil amoeba, found in a diverse range of marine, freshwater, soil and human-related environments. As an opportunistic pathogen, it is responsible for amoebic keratitis and granulomatous amoebic encephalitis in humans [37], and under free-living conditions, it grazes on bacterial biofilms [38]. Thus it is likely that A. castellanii routinely encounters anaerobic or microaerobic conditions. Furthermore, while this amoebozoon has been reported to encyst rapidly when exposed to degassing with N2 [39], it is now known to respond well to low-oxygen conditions, replicating faster under these conditions than under aerobic ones [30].

In 2010, Hug et al. reported partial sequences of a few enzymes associated with anaerobic ATP generation in publicly available expressed sequence tag (EST) data from A. castellanii [16]. Here, we report the existence a complete ‘hydrogenosomal’ type anaerobic ATP generation pathway, describe the genomic and transcript sequences of all enzymes involved, and show that they all possess classical mitochondrial targeting peptides. We show, by tandem mass spectrometry, that three of these enzymes – PFO, ASCT1B, and the [FeFe]-hydrogenase maturase HydF – are found in the mitochondria of aerobically grown cells. Our findings confirm the presence of a complete hydrogenosome-like ATP generation pathway in A. castellanii and strongly suggest that the enzymes are present within the mitochondria of this organism. Our results raise the tantalizing possibility that the mitochondrion of A. castellanii is able to act as an organelle with two metabolic modes, producing energy either aerobically, via classical oxidative phosphorylation, or anaerobically, via a hydrogenosomal-type pathway, according to the environmental conditions that the amoeba encounters.

Materials and Methods

EST assembly

454 ESTs available through the Baylor College of Medicine Human Genome Sequencing Center (http://www.hgsc.bcm.tmc.edu/ltp-archive/AcastellaniNeff/ESTs/) were assembled using CAP3 [40] and Mira [41,42].

Database searching

Partial EST sequences of [FeFe]-hydrogenase, PFO, HydF and HydG previously identified by Hug et al. [16] were retrieved by performing Basic Local Alignment Search Tool (BLAST [43]) searches against the publicly available A. castellanii expressed sequence tag (EST) library at TBestDB [44]. Genomic sequence data were obtained by performing subsequent BLASTn searches against scaffolds assembled by the Baylor College of Medicine Human Genome Sequencing Center (http://www.ncbi.nlm.nih.gov/bioproject/PRJNA20303; see Table S1 for accession numbers), using the A. castellanii ESTs as queries. As no ESTs encoding HydF or an ASCT had been identified, we used a Clostridium kluyveri HydF protein sequence (EDK34342) and Trypanosoma brucei, Fasciola hepatica and Trichomonas vaginalis ASCT sequences (EAN79240, ACF06126 and XP_001330176, respectively) as heterologous query sequences for tBLASTn searches. Subsequently, full-length cDNA sequences were obtained by performing BLASTn searches against the 454 EST data, using previously identified EST or genomic sequences as queries. The identities of hits were verified by performing BLASTx searches against GenBank. Start codons and intron positions were verified manually. Predicted mitochondrial targeting peptides were identified using TargetP [45–47].

Cell culture

Cells were maintained at room temperature, but otherwise as described in [48].

Tandem mass spectrometry

Mitochondria were isolated from aerobically grown cells, purified on sucrose gradients, and subfractionated as described.
in [49]. A whole mitochondrial fraction (SWM), a soluble protein-enriched fraction (SPE), and a mitochondrial membrane protein-enriched fraction (MPE) were separated on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) gels; the resulting lanes were excised in approximately equally sized bands and digested, as described in [49]. These fractions were separated by reverse-phase high-performance liquid chromatography (HPLC) and subjected to tandem mass spectrometry (MS/MS) as described [49]. An additional whole mitochondrial fraction that had not undergone SDS-PAGE was digested in solution (WM) and separated into fractions using strong cation exchange liquid chromatography; these fractions were resolved by reversed-phase HPLC and subjected to MS/MS. Data were acquired and analyzed against the genomic and 454 EST data using Mascot [50], as described in [51]. Of the 143 nuDNA-encoded proteins identified by MS/MS in [49], representing respiratory chain proteins (88 proteins) and non-respiratory chain proteins that contaminated preparations of respiratory complexes (55 proteins), none were known non-mitochondrial contaminants and none were confidently predicted to possess sorting signals that direct proteins to other cellular compartments, such as the endoplasmic reticulum or peroxisomes; accordingly, this protocol was deemed to have produced sufficiently pure mitochondria samples. In order to confirm that the samples used in this particular experiment were highly enriched in mitochondria, we compared the gel electrophoretic profile of the rRNA species recovered from the purified mitochondria to that of total cellular RNA, as a proxy for protein phoretic profile of the rRNA species recovered from the purified mitochondria to that of total cellular RNA, as a proxy for protein phoretic profile of the rRNA species recovered from the purified mitochondria to that of total cellular RNA, as a proxy for protein.

Phylogenetic analyses

For each protein, NCBI databases of proteins and EST sequences were searched using BLASTp or tBLASTx respectively, and added to preexisting datasets used in [16] where applicable. Preliminary alignments were made using MUSCLE [52,53], FSA [54] or MAFFT-L-INS-I [55–57] and trimmed using BMGE [58] or a script written by Dr. Daniel Gaston. Preliminary trees were made using FastTree [59], or RAxML (version 7.2.6 [60], using the Le and Gascuel [LG] model of amino acid substitution rates [61] with empirical amino acid frequencies and the gamma model of rate heterogeneity [PROTGAMMALGF]. Based on these initial analyses, long-branching clad being wide, and bacterial sequences that were identified in [FeFe]-hydrogenase analyses. Final analyses were performed both with and without these sequences. Initially, ASCT1C sequences were analyzed together with distantly homologous ASCT1B sequences, and distantly homologous HydE and HydF sequences were analyzed together; this was done to better identify paralogs in the face of widespread misannotation in GenBank. Final alignments were made using MAFFT-L-INS-I, verified manually, and trimmed using BMGE. Independent maximum likelihood (ML) trees (200) and 1000 bootstrap replicates were generated in RAxML [PROTGAMMALGF] model, and bootstrap values were mapped onto the best-scoring tree. Bayesian inference posterior probabilities were calculated using PhyloBayes [62] under the [catfix C20] model of evolution [63].

Topology tests

We tested support for various grouping topologies using the approximately unbiased (AU) test in CONSEL [64]. For each hypothesis tested, five ML trees were generated for a given constraint tree, using the PROTGAMMALGF model and the –g option in RAxML. Subsequent CONSEL analyses used the 1000 bootstrap trees initially produced to generate p-values for the best trees generated from the constrained RAxML analyses.

Results

The A. castellani genome encodes a complete anaerobic ATP generation pathway similar to that found in T. vaginalis hydrogenosomes

Hug et al. [16] had identified partial sequences of [FeFe]-hydrogenase, PFO, HydE and HydG in the A. castellane transcriptome (Table S1). We have identified corresponding genomic sequences for all four genes. Searches using a Clostridium HydF sequence and ASCT sequences from Trypanosoma brucei, Fasciola hepatica and Trichomonas vaginalis as queries yielded a HydF homolog and two possible candidates for an ASCT, homologous to the T. brucei (subfamily 1A) and the F. hepatica (subfamily 1B) enzymes. The subfamily 1A enzyme of T. brucei is homologous to succinyl-CoA:3-ketoacid-CoA transferase (SCOT), an enzyme that is widespread in mammalian and fungal mitochondria, and that catalyzes the transfer of CoA from succinyl-CoA to a 3-oxoacid. The top BLASTp hits for this candidate were SCOT homologs from Pyrobaculum pallidum and Dictyostelium discoideum, two other, ‘cellular slime mold’, amoeboids that do not appear to possess anaerobic ATP generation enzymes. In contrast, the F. hepatica-type enzyme has been described in platyhelminths and arthropods, and is homologous to bacterial 4-hydroxybutyrate.

Figure 1. Map of the genomic segment encoding [FeFe]-hydrogenase and its associated maturases. The direction of the arrows indicates the transcriptional orientation of the genes. Green, anaerobic metabolism enzyme-encoding gene located on the forward strand. Red, anaerobic metabolism enzyme-encoding gene located on the reverse strand. Gray, predicted gene encoding a product not evidently involved in anaerobic metabolism. Predicted genes annotated according to top BLAST hits in dictyBase: A. Similar to interferon-related protein PC4-like. B. Region without significant hits in either GenBank or dictyBase, but which corresponds to EST sequence and apparently contains an intron. C. Similar to molybdenum cofactor synthesis protein 1. G. Similar to molybdenum cofactor synthesis protein 2. H. Region with similarity to sequences annotated as hypothetical protein. E. Similar to RNA-binding region RNP-1 domain-containing protein. F. Similar to molybdenum cofactor synthesis protein 1. G. Similar to molybdenum cofactor cofactor synthesis protein 2. H. Region with similarity to sequences annotated as hypothetical protein in GenBank, but without tBLASTx hits in dictyBase. I. Similar to PHD Zn finger-containing protein. J. Low similarity to vaso dilator-stimulated phosphoprotein. K. Region without significant hits in either GenBank or dictyBase, but which corresponds to EST sequence and apparently contains an intron. doi:10.1371/journal.pone.0069532.g001
CoA-transferases; we were unable to find homologs of this enzyme in the *Polysphondylium pallidum* or *Dictyostelium* genome sequences available through dictyBase [65]. Accordingly, we concluded that the *F. hepatica* enzyme hit was the more likely candidate to function in a pathway with the other anaerobic enzymes we had discovered.

The *A. castellanii* genome encodes a single adrenodoxin-like [2Fe-2S] ferredoxin, homologous to eukaryotic mitochondrial ferredoxins, which may function as the electron mediator from PFO to [FeFe]-hydrogenase; and STK, which may perform dual functions in the TCA cycle and in anaerobic ATP generation. Full-length EST sequences for each of these enzymes were retrieved from 454 pyrosequencing data, confirming the locations of spliceosomal introns in the genomic sequences. All of the genomic sequences contained canonical 5′-GT-3′ spliceosomal introns, refuting the possibility that the genes we identified originated from bacterial contamination of the transcriptomic and genomic data (see Table S1 for the list of accession numbers).

Interestingly, the genes encoding [FeFe]-hydrogenase and all three maturases are encoded within a single, 50-kb stretch of the genome (Figure 1). Within this region, 11 other predicted genes were found that had homologs returned by BLAST searches. With the exception of two genes encoding hypothetical proteins, all of the predicted genes had significant tBLASTx hits (with an E-value \#10 \wedge 3) to one of more of the amoebozoan genomes.

Figure 2. N-termini of anaerobic energy generation enzymes in *A. castellanii*, showing putative mitochondrial targeting peptides (mtTPs). Putative mtTPs were predicted by TargetP, and are shown underlined and bold. N-termini of bacterial and eukaryotic homologues are shown for comparison; bacterial homologues lack targeting peptides. Positively charged residues in the predicted mtTPs are shown in red; hydrophobic residues are shown in blue. Arginine residues at positions 2, 23 or 210, and hydrophobic residues at position 28, believed to be important in determining the cleavage site [66], are marked with an asterisk. P, TargetP mitochondrial targeting probability.

Peptides diagnostic of PFO, ASCT1B and HydF were detected in the mitochondrial protein fractions by tandem mass spectrometry (Table 2, Figure 3).

Thirty unique PFO-specific peptides were identified in the WM, SWM and SPE fractions, with a high ion score (1457), evidence that PFO is present at a relatively high abundance in *A. castellanii* mitochondria even under aerobic conditions. No PFO-specific peptides were identified in the MPE fraction; these findings are consistent with PFO in *A. castellanii* being a soluble matrix protein, in contrast to that of *T. vaginalis*, which is bound to the hydrogenosomal membrane [67]. ASCT1B was similarly well represented in the mitochondrial proteome (ion score: 1900, 17 unique peptides).

A single peptide from the [FeFe]-hydrogenase maturase HydF was identified, as were three peptides from ferredoxin. No peptides corresponding to [FeFe]-hydrogenase, or to the two other [FeFe]-hydrogenase maturases, were recovered.

In addition, we performed immunogold labeling experiments on *A. castellanii* cells that had been exposed to anaerobic conditions for 6 or 24 hr, using an antibody raised against *A. castellanii* [FeFe]-hydrogenase (Methods S1). Antibody staining in these cells was elevated in mitochondria (approx. 2.9-fold higher than in the cytosol, and approx. 1.7-fold higher than in the nucleus), consistent with the presence of a predicted mitochondrial targeting peptide for [FeFe]-hydrogenase (Figures S2, S3, S4), although the high levels of antibody required and the degree of cross-reaction in other cellular locations suggest that optimal expression conditions remain to be established for [FeFe]-hydrogenase in *A. castellanii*.

doi:10.1371/journal.pone.0069532.t002

Available through dictyBase. None of these additional genes has any obvious function in anaerobic respiration.

TargetP predicted high probabilities of mitochondrial localization, and identified putative targeting peptide cleavage sites, for all of the anaerobic ATP generation enzymes (Figure 2). The predicted mitochondrial targeting peptides (mtTPs) are rich in hydrophobic and positively charged amino acids, consistent with the amphipathic helix structure that mitochondrial targeting peptides are known to adopt [66]. The mtTPs have arginine residues at positions −2, −3 or −10 relative to the cleavage site, as well as positively charged residues at position −8 in the latter case. Such residues are believed to be important in determining the site of targeting peptide cleavage [66]. The composition of the predicted targeting peptides is consistent with those predicted by TargetP for other nuclear-encoded proteins known to be mitochondrially targeted in *A. castellanii*, such as mitochondrial malate dehydrogenase, dihydrolipoamide dehydrogenase and isocitrate dehydrogenase (data not shown).

PFO, ASCT1B and the [FeFe]-hydrogenase maturase HydF are present in the mitochondrial proteome

Peptides diagnostic of PFO, ASCT1B and HydF were detected in the mitochondrial protein fractions by tandem mass spectrometry (Table 2, Figure 3).

Evolutionary histories of anaerobic ATP generation enzymes

Previous analyses of [FeFe]-hydrogenase phylogenies have failed to recover eukaryotes as a monophyletic clade [16,30,68,69]. Our results (Figure 4), which include sequences from a larger number of eukaryotic taxa than were previously available, are consistent with these findings, in that we recover at least three distinct eukaryotic clades. While our trees suffer from the same poor resolution (i.e. low bootstrap support for many branches) that has been reported in previous analyses, it is possible to conduct approximately unbiased (AU) topology tests to determine whether the data have sufficient information to reject alternative phylogenetic hypotheses using an alpha-level of 0.05 as the significance threshold. The hypotheses tested are shown in Table 1 and include tests for the monophyly of eukaryote sequences as a whole, the grouping of *A. castellanii* sequences with homologs from other amoebozoans, and tests for grouping of eukaryotic and/or *A. castellanii* sequences with α-proteobacterial sequences (as expected if they were of mitochondrial origin). These tests show, for example, that monophyly of the *A. castellanii* sequence with other amoebozoan homologs, such as the sequence from *Mastigamoeba balanuathi* or the *Entamoeba histolytica* sequence, can be rejected, whereas eukaryote monophyly itself cannot be rejected. Preliminary RAxML and FastTree analyses recovered one unusually long-branching eukaryotic/bacterial clade, corresponding to the major [FeFe]-hydrogenase Clade B described in Hug et al. [16], which includes the *M. balanuathi*, both *Trimastix pyriforinis*, and one of the *E. histolytica* enzymes. Separate analyses were performed excluding the taxa in this clade (Figure S5). Removing this clade did not alter the overall topology enough to recover eukaryote monophyly; again, however, in AU tests using this dataset, eukaryote monophyly was not rejected.

The only previous phylogenetic analysis of [FeFe]-hydrogenase maturases [16] was notable in that it recovered eukaryote monophyly for all three enzymes, despite this not having been the case for [FeFe]-hydrogenase itself – even accounting for the lack of known sequences of these enzymes in some eukaryotes. This observation also holds true for our analyses (Figures S6, S7, S8), despite the additional eukaryotic sequence data that have become available in the interim. Although *Spiroplasma tortori* groups with α- and β-proteobacteria in the HydE tree (Figure S6), this position has low bootstrap support and, as with the other two maturases, topology tests (Table 1) do not reject eukaryote monophyly for HydE. In contrast with the topology tests for [FeFe]-hydrogenase, PFO and ASCT1B, a specific grouping of eukaryotes and α-proteobacteria (as expected if the enzymes were of mitochondrial origin) is not rejected by topology tests (Table 1). Within the main eukaryotic clade, low support precludes drawing conclusions about internal relationships, including that of *A. castellanii*; monophyly of *A. castellanii* and *M. balanuathi* is not rejected by topology tests for any of the maturases.

Previous phylogenetic analyses of PFO reached different conclusions as to the recovery of eukaryote monophyly [16,34]. Our analyses excluded a long-branching *Monocercomonades* sequence that may have distorted the topology recovered by Hug et al. [16]; consequently, we recover eukaryotic monophyly (Figure 5), a finding consistent with that of Horner and colleagues [34]. As in the case of [FeFe]-hydrogenase, a hypothetical *Acanthamoeba Entamoeba* clade was rejected by

topology tests; but an Acanthamoeba+Mastigamoeba clade was not. However, large groupings within the eukaryote clade have poor support, preventing the inference of clear internal relationships.

A previous neighbor-net analysis of ASCT1B and ASCT1C sequences [23] recovered a monophyletic cluster of animal sequences, representing the only eukaryotes known to possess ASCT1-like sequences at that time. Our analyses include additional animal sequences, as well as sequences from a number of other lineages. Monophyly of all of these eukaryote sequences is rejected in topology tests (Table 1), as is the grouping of α-proteobacteria with any of the major eukaryote groups. However, both the grouping of A. castellanii with the aerobic flagellate Malawimonas jakobiformis as well as the branches separating this clade from away from opisthokonts and Blastocystis have low bootstrap support (Figure S9), and an alternate position of this organism, grouping with opisthokonts and Blastocystis, is not rejected.

Discussion

Acanthamoeba castellanii is known to inhabit aerobic environments and to produce energy via oxidative phosphorylation; it possesses a mitochondrion with a functional TCA cycle and electron transport chain similar to those found in other aerobic eukaryotes [49,70]. Nevertheless, it inhabits a wide range of soil, aquatic, and man-made environments, and it is likely that it encounters low-oxygen conditions with some frequency. An organism with such a lifestyle would likely derive significant survival benefit from being able to function under a wide range of conditions, including periods of anoxia. Here, we present the first case of a complete hydrogenosome-like ATP generation pathway with predicted mitochondrial targeting in a habitually aerobic eukaryote, and show that several of its key enzymes are present in the mitochondria. Our work provides the first evidence supported by localization data for a mitochondrion possessing the metabolic components of a ‘hybrid’ organelle, which may enable it to adopt functions in oxidative phosphorylation or anaerobic metabolism according to the conditions that it encounters. The existence of such organelles in an extant organism immediately suggests a possible sequence of events in the first steps leading to the emergence of hydrogenosomes. Upon acquiring an anaerobic energy-generating pathway, a previously obligate aerobe would be able to thrive in a more diverse range of habitats, as well as surviving temporal fluctuations in oxygen levels. Subsequently, descendents of such a cell inhabiting exclusively low-oxygen environments, with a reduced need to perform oxidative phosphorylation, might lose components of the electron transport chain, as well as other mitochondrial functions (Figure 6).

We have confirmed the presence in A. castellanii of a complete anaerobic ATP generation pathway similar to that found in hydrogenosomes. All of these enzymes are predicted to have mitochondrial localization, and we confirm this localization for the characteristic hydrogenosomal energy enzymes PFO, ASCT1B, HydF and [FeFe]-hydrogenase. It should be noted that we cannot exclude the possibility of a dual mitochondrial and cytosolic localization of these enzymes; nevertheless, the presence in mitochondrial fractions of PFO, ASCT1B and HydF, and the elevated localization of [FeFe]-hydrogenase within the mitochondria, suggests that these organelles can function as a site of anaerobic respiration in A. castellanii. Further research should elucidate the conditions under which this pathway is induced in A. castellanii, and the interplay between anaerobic respiration and encystation as different – or perhaps complementary – survival modes in this organism. In addition, the detection of PFO, ASCT1B and HydF peptides in mitochondrial fractions purified...
from aerobically grown cells raises the possibility that some or all of these enzymes may be upregulated in response to environmental factors other than oxygen concentration.

The most intriguing question raised by this study concerns the origin of these genes. The physical proximity of [FeFe]-hydrogenase and its three maturases in the genome might suggest the lateral transfer of a single bacterial operon as an acquisition mechanism. However, the presence of so many interspersing genes and the absence of a clear bacterial donor candidate argue against a single, recent transfer from bacteria. Topology tests reject the grouping of *A. castellanii* and *β*-proteobacteria (with remaining euukaryotes unconstrained) for [FeFe]-hydrogenase, PFO and ASC13B. This result is consistent with previous studies, which recover at least two independent origins for [FeFe]-hydrogenase, and specifically reject *β*-proteobacterial ancestry for [FeFe]-hydrogenase in topology tests [16].

Eukaryote monophyly is recovered for two of the maturases and for PFO, and is not rejected in topology tests for [FeFe]-hydrogenase and the remaining maturase. This finding might seem consistent with the hydrogen hypothesis, which holds that the original endosymbiont that gave rise to mitochondrion-related organelles within eukaryotes was a facultative anaerobe possessing [FeFe]-hydrogenase and the remaining maturase. This finding might seem consistent with the very small number of homologs reported in contemporary *β*-proteobacteria. However, if this is the case, then (1) the patchy distribution of anaerobic ATP generation enzymes among eukaryotes in general, (2) the rejection of monophyly of *A. castellanii* with two other amoebozoans for [FeFe]-hydrogenase, and (3) the absence of genes for these enzymes in the genomes of other members of Amoebozoa, remain to be explained.

Intriguingly, the existence of monophyletic eukaryotic clades with unusual internal topology has been reported for other enzymes with patchy distributions among eukaryotes. The authors of these studies proposed multiple lateral transfers between eukaryotes as a hypothesis to explain patchy distributions and unexpected phylogenetic relationships for other enzymes found in both aerobic and anaerobic protists [13,72–76]. This mode of acquisition would provide an attractive alternative scenario for the acquisition of anaerobic metabolism genes; the transfer of genes between eukaryotes would remove the need for the acquisition of eukaryotic regulatory sequences for the enzymes in the recipient, and would account for the distribution of anaerobic ATP generation enzymes in extant eukaryotes. Furthermore, it would provide an elegant explanation for the common pool of anaerobic ATP generation enzymes found in anaerobic eukaryotes [7].

Frustratingly, the lack of phylogenetic resolution in much of the tree, including for internal eukaryote relationships and for the position of *A. castellanii* itself, does not allow us to draw strong inferences that would help us to distinguish among competing hypotheses as to the origin of anaerobic enzymes in *A. castellanii*.

Our work cemented the possibility, initially raised by Hug et al. [16], that anaerobic ATP generation enzymes might be more widespread among eukaryotes than previously thought, not being limited to anaerobic or microaerobic lineages. It also highlights the importance of exploratory sequencing efforts focusing on a wide range of organisms. So far, anaerobic energy enzymes have been described in two non-photosynthetic organisms, *A. castellanii* and *N. gruberi*. As an opportunistic human pathogen that also harbours pathogenic bacteria, and a close relative of an opportunistic human pathogen, respectively, both of these organisms have links to human health, making them attractive targets for sequencing efforts. However, the more important link between them is likely their lifestyle, which exposes them to a wide range of habitats that vary in oxygen concentration, a lifestyle likely made possible by the anaerobic energy enzymes they have acquired. Free-living soil protists are relatively poorly studied, and investigations into the metabolic complements of a wider range of such organisms will reveal whether these hybrid organelles are found more commonly in nature than previously suspected.

**Supporting Information**

**Methods S1** Methods relating to results shown in Figures S2–S5.

**Figure S1** Assessment of mitochondrial purity by comparing rRNA profiles of total cellular RNA and total mitochondrial RNA from *A. castellanii*. A) An EtBr-stained 6% (w:v) acrylamide, 7 M urea gel loaded with varying quantities of total cellular (T) and total mitochondrial (M) RNA. Numbers are quantities of RNA (in μg) loaded in each lane. The profiles of large rRNA species in T and M are distinct, suggesting that the mitochondrial fraction is relatively free of contaminating cytosolic rRNA (and presumably cytosolic ribosomal proteins). *A. castellanii* cytosolic (c) and mitochondrial (m) LSU and SSU species are identified (note that the cLSU is split). B) 10% acrylamide gel as in A). Note that a mitochondrial 5S rRNA (m5S) is visualized in the M lane and, to a much lower extent, in the T lane. A band corresponding in size to cytosolic 5.8S rRNA is visible in an overloaded M lane; however, no cytosolic 5S (c5S) is detectable.

**Figure S2** Western blot showing recognition of the recombinant [FeFe]-hydrogenase by the homologous anti-[FeFe]-hydrogenase antibody. Lanes 1, 3, 5 and 7: inclusion bodies from C41(DE) cells expressing empty pET-16b vector. Lanes 2, 4, 6 and 8: inclusion bodies from C41(DE) cells expressing recombinant *A. castellanii* [FeFe]-hydrogenase from pET-16b. Lanes 1 and 2: anti-His-tag antibody, exposed for a shorter period of time than lanes 3–8 in order to avoid overexposure. Lanes 3 and 4: anti-[FeFe]-hydrogenase antibody only. Lanes 5 and 6: anti-[FeFe]-hydrogenase antibody incubated with inclusion bodies from C41(DE) cells expression empty pET-16b. Lanes 7 and 8: anti-[FeFe]-hydrogenase antibody incubated with inclusion bodies from C41(DE) cells expressing recombinant *A. castellanii* [FeFe]-hydrogenase from pET-16b.

**Figure S3** Immunogold localization of [FeFe]-hydrogenase in *A. castellanii* trophozoites exposed to anaerobic conditions for 24 hr. A. Whole cell fixed for immunogold staining; scale bar, 500 nm; this image has been cropped in order to show only the whole cell from which the insets shown were derived. B. and C. Magnified sections from the cell depicted in (A), showing gold particles corresponding to [FeFe]-hydrogenase localization; scale bar, 500 nm. D. Mean density of immunogold labeling in the cytosol, nucleus and mitochondria (B cells). Brightness and contrast have been adjusted in each image to enhance visibility of the mitochondria and gold particles.
