Case Report

A 54-year-old male presented to the emergency department with complaints of acute onset of abdominal pain and vomiting. He also had history of intermittent dull aching pain in the abdomen since fifteen days prior to this acute episode. The patient denied history of taking any drugs. He had no history of drug allergy, asthma or allergic rhinitis. There was no history of allergy or atopy in family members. There was no past history of fever, diabetes, tuberculosis, asthma, hepatitis or ischemic heart disease.

Physical examination revealed a slightly distended abdomen with rigidity and tenderness. There was no organomegaly. Laboratory investigations showed Hb-11.4 g/dL and total leucocyte count 9.8 x 10^9/L. Differential count revealed polymorphs -47%, lymphocytes -24% and eosinophils -29%. Absolute eosinophil count was 2842/mm^3 (2.8 x 10^9/L). Other laboratory studies with serum IgE were within normal limits.

Chest X-ray was within normal limits. Abdominal X-ray displayed multiple air-filled levels in the small intestine. Emergency laparotomy was performed with a midline incision in view of increasing distension and tenderness of abdomen. Exploration revealed multiple ileal strictures with proximal dilatation. Segmental resection of the ileum and end-to-end anastomosis was performed and a resected specimen sent for histopathology.

Gross examination revealed a segment of small intestine about 24 cm in length with three strictures in the ileum and proximal dilatation of intestine with congestion of serosa (Figure 1). On cutting open, a narrowed lumen due to stricture with congestion of mucosa was noted (Figure 2). Peripheral surgical margins were unremarkable.

Multiple sections of the resected specimen showing layers of small intestine (Figure 3) were studied. All the layers of intestine showed diffuse and dense infiltration of eosinophils of >40-60 eosinophils/hpf (Figure 4). All the coats showed congestion and serosa were covered by inflammatory exudates. The section through stricture showed fibrosed wall with dense eosinophilic infiltration (Figure 5).

Final histological diagnosis of eosinophilic enteritis with stricture was made presenting as acute intestinal obstruction with peritonitis. The patient recovered well and was free of gastrointestinal symptoms during the follow up period of one year. During this period, upper GI endoscopy and biopsy were performed. These showed no eosinophilic infiltration in the stomach. Postoperative stool examination was negative for ova, cyst or worm infestation on two separate occasions. Occult blood in stool was negative. The patient was given oral prednisolone 10 mg daily for six weeks and tapering thereafter, resulting in a normal hematologic examination.

Discussion

Primary eosinophilic gastroenteritis is defined as a disorder that primarily affects the gastrointestinal tract with eosinophil rich inflammation in the absence of a known cause for eosinophilia, including drug reaction, parasitic infections and malignancy. Eosinophilic gastroenteritis was first described in 1937 by Kajiser. In 1970, Klein classified the disease according to the predominance of eosinophilic infiltration in different layers of the intestinal wall. Involvement of different layers of the intestinal wall usually gives rise to different clinical manifestations. The mucosal form of eosinophilic enteritis (most common variant) is characterized by vomiting, abdominal pain, and diarrhea, blood loss in stools, iron deficiency anemia, malabsorption and protein losing enteropathy. The muscularis form is characterized by infiltration of eosinophils predominantly in the muscle layer, leading to the thickness of the bowel wall due to fibrosis, which may result in gastrointestinal obstructive symptoms. Our patient presented with this form of the disease secondary to stricture. The mucosal form occurs in a minority of patients with eosinophilic enteritis with ascites with higher peripheral eosinophils counts compared with the other forms. The serosal form is characterized by exudative ascites. In our case, eosinophils infiltrated all the three layers of the intestinal wall and thickening of the muscle layer leading to stricture causing intestinal obstruction.
Although eosinophilic enteritis can involve any part of the gastrointestinal tract, the stomach and duodenum are the most common sites of involvement.2,3,6,8 Eosinophilic gastroenteritis is an extremely rare disease, with less than 200 patients described in the literature. The largest published series includes only 40 patients.8,9 Because the pathogenesis and etiology of the disease are not well understood, no standards for the diagnosis of eosinophilic enteritis exist. Tally et al.5 have identified three main diagnostic criteria: i) presence of gastrointestinal symptoms; ii) biopsies demonstrating eosinophilic infiltration of one or more areas of the gastrointestinal tract; iii) no evidence of parasitic/extraintestinal disease. It was reported that peripheral eosinophilia is uniformly associated with the eosinophilic enteritis.7,11 Peripheral eosinophilia has been reported in up to 80% of cases by Tally et al.5 However, the definite diagnosis of eosinophilic enteritis requires histological evidence of eosinophilic infiltration.2 Laparotomy or laparoscopic full thickness biopsy is often required to make a diagnosis, especially when there is involvement of the muscular layer, as small biopsies by gastroscopy or colonoscopy are likely to yield a negative result. Patients with predominantly serosal disease have higher eosinophils count (average 8000/dL) than patients with mucosal disease (average 2000/dL) and muscle layer disease (average 1000/dL).12 Moreover, a study at the Mayo clinic showed that 50% of patients with eosinophilic enteritis reported a history of allergy, such as asthma, allergic rhinitis, urticaria, drug allergy and eczema.3 If eosinophilic enteritis is considered a form of hypersensitivity reaction, the exact nature of the allergens requires investigation. Food, as a natural allergen, is considered to be associated with eosinophilic enteritis. Nevertheless, clinical studies have shown no relationship between food and allergy and eosinophilic enteritis.13 Our patient did not have any personal or family history of food allergy.

Treatment with a steroid is the mainstay in the management of eosinophilic enteritis. In the study by Chen MJ et al.,6 all 13 patients had successful resolution of symptoms within two weeks. Other therapies have been tried including sodium chromoglycate, ketotifen14 and montelucast.15 However, their long-term effectiveness is questionable and requires more prospective clinical trials. Foroughi S et al.16 reported success in an open-label study of 9 patients treated with omalizumab, a monoclonal anti-IgE antibody. Immunosuppressive with azathioprine can be used as an adjunct to steroids.17 Sodium chromoglycate, a mast cell stabilizer may be used to prevent release of mast cell toxic material; release of histamine and leukotrienes also reduces absorption of antigens by the small bowel. It can used mainly to treat milk allergy and other GI allergic reactions in children, with as such no role in reducing stricture associated with eosinophilic enteritis.17 Although surgeons should avoid unnecessary surgery, surgical interventions may sometimes be required when a definite diagnosis cannot be made, or when complications like perforation or obstruction occur, as in our case. Since the natural history of eosinophilic enteritis has not well documented, long-term follow up is required.

**Conclusions**

Eosinophilic enteritis is a rare, poorly understood condition presenting with a bizarre spectrum of unexplained symptoms mimicking other acute abdominal conditions. Hence, eosinophilic enteritis is a diagnostic dilemma and clinical presentations with investigations are only contributory. Presentation with acute abdomen is even less common, and surgeons should remain vigilant with this rare cause in mind.
