Strong Coupling Expansion for the Conformal Pomeron/Odderon Trajectories

Abstract

From the perspective of AdS/CFT the Pomeron is identified with a Reggeized Graviton, while the Odderons correspond to Reggeized anti-symmetric $AdS_5$ Kalb-Ramond tensor-fields. In this paper, we consider the strong coupling expansion of the dimension of the leading twist operators dual to these Regge trajectories, $\Delta(j)$, to determine its analytic continuation in $j$ beyond the diffusion limit. In particular, we compute the strong coupling expansion of the intercept to order $\lambda^{-3}$, where $\lambda$ is the t’Hooft coupling, for both the Pomeron, which is $C = +1$ crossing-even, and the “Odderons”, which are the leading $C = -1$ crossing-odd Regge singularities. We discuss the spectral curves of the class of single-trace operators to which these string modes couple.
1 Introduction

\textit{AdS/CFT correspondence} \cite{1, 2, 3, 4}, has provided a useful perspective on several domains of non-perturbative QCD, such as heavy ion collisions, low-energy meson dynamics, and high energy scattering. In particular, at strong coupling the leading Pomeron exchange has been identified as a \textit{Reggeized AdS Graviton}, in the planar approximation to $\mathcal{N}=4$ Super Yang Mills (SYM) Theory \cite{5}.

A crucial observation made in \cite{5} is the role played by the analytic continuation in the $\Delta - j$ plane for anomalous dimensions, $\gamma(j) = \Delta(j) - j - \tau$, for the leading twist operators as a function of $j$ and the 't Hooft coupling $\lambda = g^2 N_c$. In a conformal field theory, the inverse curve in the “Dimension-$j$” plane, $j(\Delta)$, plays a central role analogous to the traditional Regge pole trajectory $\alpha(t)$ in “Energy-$j$” plane. As a spectral curve, $\Delta(j)$ has a remarkable symmetry due to conformal invariance: the inverse curve, $j(\Delta)$, is symmetric under $\Delta \leftrightarrow 4 - \Delta$, \footnote{More succinctly stated, conformal symmetry implies a $j$-plane trajectory as a function of $\Delta(\Delta - 4) = M^2_{ads} R^2_{ads}$ just as Lorentz invariance implies Regge $j$-plane trajectories as a function of $\alpha' t$. We will occasionally refer to $j(\Delta)$ as the “conformal Reggeon spin”, or simply “Reggeon spin”.} with a minimum at $\Delta = 2$, as shown in Fig. 1 for the leading twist-2 spectral curve. At integer $j$ this symmetry relates operators to shadow operators in the conformal field theory. The value of $j$ at this minimum, $j_0(\lambda)$, corresponds to the location of the conformal Regge intercept associated with a given spectral curve $\Delta(j)$. In strong coupling, the Pomeron intercept \cite{5, 6},

\begin{equation}
\alpha_P = j_0(\lambda) = 2 - \frac{2}{\lambda^{1/2}} + O(1/\lambda),
\end{equation}

was determined by perturbing the spectral curve $\Delta_P(j)$ about the graviton at $j = 2$ in the super-gravity limit. The same principle can be applied to weak coupling, with the minimum identified with the BFKL Pomeron intercept \cite{7, 8, 9, 10, 11}

\begin{equation}
\alpha_P = j_0(\lambda) = 1 + \frac{4 \ln 2}{\pi} \lambda + O(\lambda^2).
\end{equation}

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{fig1.png}
\caption{The conformal Regge trajectory reproduced from Ref. \cite{5} : Schematic form of the $\Delta-j$ relation for twist-2 spectral curve at weak ($\lambda \ll 1$) and strong coupling ($\lambda \gg 1$).}
\end{figure}
A major challenge in $\mathcal{N} = 4$ SYM is to determine this intercept $j_0(\lambda)$ for all $\lambda$ in the large $N_c$ approximation and to apply this analysis to other trajectories \[12\].

In this paper we apply an expansion procedure for spectral curves, that describes short strings in AdS $[13] [14] [15]$, to improve the strong coupling expansion for both the leading conformal Pomeron (C =+1) and Odderon (C= -1) trajectories. For the Pomeron this is a simple extension of earlier results $[10] [17] [18] [19]$, while the application to the Odderon trajectory $[20] [21]$ is new. For $\mathcal{N} = 4$ SYM, the C= +1 exchange is associated with exchange of local operators with ± light-cone components,

$$O_P^\pm(j, k) = Tr[F^{\pm\pm}(D^\pm)^{j-2} F_{\perp}^\pm Z^k] + \cdots,$$  \hspace{1cm} (1.3)

with $j = 2, 4, 6, \cdots$ and $k = 0, 1, \cdots$. Here, $Z$ is a scalar field with $SU(4)$ R-charge. The leading Pomeron has $k = 0$, but we extend known results to the case of R-charge exchange with $k \neq 0$. Due to supersymmetry, the analysis can be simplified by relating the relevant spectral curves to that for single-trace operators in the $sl(2)$ sector, symbolically expressed as $Tr[(D^\pm)^{j-2} Z^{k+2}] + \cdots$ $[22] [23]$. For the case of the $C = -1$ Odderon trajectory, we shall show how similar techniques can also be applied\[2\].

We shall restrict our attention to the pure conformal limit and begin here by briefly describing the Regge limit in the context of conformal field theories $[24] [25] [20] [10]$. Consider the connected component for a four point correlation function of primary operators $O_i$ of dimension $\Delta_i$. Defining $x_{ij} = x_i - x_j$, we have

$$A(x_i) = \langle O_1(x_1) O_2(x_2) O_3(x_3) O_4(x_4) \rangle_c = \frac{1}{(x_{12}^2 x_{34}^2)^{\Delta_1(x_{24}^2)^{\Delta_3}}} F(u, v),$$ \hspace{1cm} (1.4)

where

$$u = \frac{x_{12}^2 x_{34}^2}{x_{13}^2 x_{24}^2}, \quad v = \frac{x_{14}^2 x_{23}^2}{x_{13}^2 x_{24}^2},$$ \hspace{1cm} (1.5)

are the cross ratios and for simplicity we have assumed $\Delta_1 = \Delta_2$ and $\Delta_3 = \Delta_4$. We need to examine the double light-cone limit of vanishing $x_{12}^2$ and $x_{34}^2$, which corresponds to $u \to 0$ and $v \to 1$ in a Minkowski setting. From the perspective of light-cone OPE, this limit can be reached by scaling $x_1^+ \to \lambda x_1^+$, $x_2^+ \to \lambda x_2^+$, $x_3^- \to \lambda x_3^-$, $x_4^- \to \lambda x_4^-$ with $\lambda \to \infty$, keeping the causal relations $x_{14}^2, x_{23}^2 < 0$, as illustrated in Fig. 2. In a frame where $x_{1\perp} = x_{2\perp}$ and $x_{3\perp} = x_{4\perp}$, this corresponds to approaching the respective null infinity while keeping the relative impact parameter

$$b_\perp = x_{1\perp} - x_{3\perp},$$ \hspace{1cm} (1.6)

fixed. In terms of the cross ratios, this corresponds to $u \to 0$ and $v \to 1$, with $(1 - v)/\sqrt{u}$ fixed. Alternatively, defining $u = z \bar{z}$ and $u = (1 - z)(1 - \bar{z})$ with $z = \sigma e^\rho$ and $\bar{z} = \sigma e^{-\rho}$, the precise Regge limit can be specified by $\sigma \to 0$ for fixed $\rho$.

Using Regge theory the leading behavior of the reduced correlation functions $F$ can be determined by the intercept $j_0$, computed from the corresponding leading spectral curve $\Delta(j)$ described earlier, with a general form

$$F(\sigma, \rho) \approx f(\rho) \frac{\sigma^{1 - j_0}}{|\ln \sigma|^{3/2}}.$$ \hspace{1cm} (1.7)

\[2\] Preliminary result was first reported at the “Low-x Workshop”, 2013, Rehovot and Eilat, Israel $[21]$. 3
This is entirely analogous to conventional Regge theory where the spectrum of Regge trajectories determines high energy scattering amplitudes.

The paper is organized as follows. In Sec. 2 we will review the dictionary that translates the Regge description from the language of CFT and OPE into scattering amplitudes in AdS space. This will allow us to proceed directly within the framework of CFT’s without explicit recourse to the AdS/CFT correspondence. Nonetheless reference to AdS space can and will be made to provide additional intuition. In Sec. 3 we analyze the Pomeron intercept beyond the “diffusion limit”, (1.1), leading to a systematic expansion for the Pomeron intercept in $\lambda^{-1/2}$. A similar analysis is done for Odderons in Sec. 4. In particular, we clarify how one of the Odderon solutions has intercept that remains fixed at 1 to all orders in $1/\sqrt{\lambda}$. These results are summarized and discussed in Sec. 5 where we also clarify further the all-coupling formula proposed by Basso in [15], and its possible generalization.

2 Conformal Regge Representation

While a conformal Regge analysis can be presented entirely in a CFT language [24, 25, 26, 16], it is often useful to follow the earlier derivations in invoking a scattering process in AdS [5, 27, 28, 29, 30]. Although both approaches are equivalent, they offer separate intuitive frameworks.

Regge Theory from CFT Partial Wave Expansion: The t-channel OPE conformal partial-wave expansion for the connected component of a 4-point function is given by a sum over conformal blocks,

$$F(u, v) = \sum_j \sum_\alpha c^{(12), (34)}_{\alpha, j} G(j, \Delta_\alpha(j); u, v).$$  \hspace{1cm} (2.1)

For the Regge limit (on the light cone), these are Minkowski conformal blocks, defined with appropriate boundary conditions, or equivalently, as analytic continuation from Euclidean space as explained in
Refs. [24, 25, 31]. Although, for planar $\mathcal{N} = 4$ SYM in the Regge limit, we shall restrict the sum to single-trace conformal primary operators, a completely general representation can be found by introducing basis function for the principle unitary conformal representation and expanding the amplitude as

$$ F(u, v) = \sum_j \int_{-\infty}^{\infty} \frac{d\nu}{2\pi} a(j, \nu) G(j, \nu; u, v). $$

(2.2)

This group representation combines a discrete sum in the spin $j$ and a Mellin transform in a complex $\Delta$-plane, with $\Delta = 2 + i\nu$, as explained by Mack [32] and others. The conformal harmonics, $G(j, \nu; u, v)$, are eigen-functions of the quadratic Casimir operator of $SO(4, 2)$. To recover the standard conformal block expansion, it is conventional to close the contour in the lower-half $\nu$-plane (equivalently, closing the contour in $\Delta$-plane to the right), picking up only dynamical poles in $a(j, \nu)$, at $\nu(j) = -i(\Delta(j) - 2)$. After summing over these pole contributions, one arrives at the conformal partial wave expansion (2.1), which also serves as an OPE. These dynamical poles correspond to all allowed conformal primaries, $O_{\Delta(j)}$, with spin $j$ and dimension $\Delta(j)$.

We are now faced with a discrete sum over spin $j$. A distinguishing feature of the Regge limit is the fact that the conformal harmonics,

$$ G(j, \nu; u, v) \sim \sigma^{1-j} \Omega_{\nu}(\rho), \quad \Omega_{\nu}(\rho) = \frac{1}{4\pi^2} \nu \sin(\nu\rho) \sinh \rho, $$

(2.3)

are more and more divergent for increasing $j > 1$ as $\sigma \to 0$. Therefore one cannot take the Regge limit term by term in (2.2). The traditional Regge hypothesis is that this sum can be evaluated by representing the partial wave expansion by the Sommerfeld-Watson transform in the analytic $j$-plane. For conformal Regge theory, this step leads to a double-Mellin representation [24, 25, 26],

$$ F(u, v) = \int_{-\infty}^{\infty} \frac{dj}{2\pi i} \int_{-\infty}^{\infty} \frac{d\nu}{2\pi} a(j, \nu) G(j, \nu; u, v), $$

(2.4)

where the contour in $j$ is to stay to the right of singularities of $a(j, \nu)$. Note that in (2.4) we must consider separate expressions for even or odd spin values, which will correspond to $C = \pm 1$ contributions respectively. While a direct proof of this $j$-plane representation is lacking for CFT’s in general, it has been shown to hold at strong coupling on the basis of the AdS/CFT correspondence for $\mathcal{N} = 4$ SYM [5] and at weak coupling in the BFKL limit [24, 25]. Moreover it is a natural assumption in order that non-conformal deformation give back the traditional Regge representation. This double-Mellin representation for conformal Regge theory leads to a meromorphic representation in the $\nu^2 - j$ plane, with poles specified by the collection of allowed spectral curves, $\Delta_\alpha(j)$. Still we should emphasize that this conformal “Regge pole hypothesis” is similar but is neither identical or a consequence of the conventional Regge theory. The conventional Regge $j$-plane analyticity with moving singularities in the $j - t$ plane, is replaced by analyticity and moving singularities in this $j - \nu^2$ plane. In Ref. [5] this distinction is clearly delineated.

---

3We have absorbed factors coming from Plancherel measure, etc., into the partial-wave amplitude $a(j, \nu)$ and will also normalize the conformal harmonics, $G(j, \nu; u, v)$, so it eventually leads to conformal blocks with conventional normalization. It has also been demonstrated in [24] how the CFT “Mellin-representation” can be expressed in this group-theoretic form.

4Due to conformal invariance, the integrand is even in $\nu$, or, equivalently, symmetric in $\Delta \leftrightarrow 4 - \Delta$. The contour can be closed either in the upper or the lower half $\nu$-plane. The poles in the upper half $\nu$-plane corresponds to “shadow” operators.
by introducing a confining deformations of the Poincare patch of AdS space which interpolate smoothly between conformal and non-conformal Regge theory.

As an illustration, let us re-consider the $C = +1$ case and focus on the contribution from a single conformal Pomeron pole in $\nu^2$,

$$a(j, \nu) = \frac{r(j)}{\nu^2 + (\Delta(j) - 2)^2},$$

(2.5)

characterized by a spectral curve $\Delta(j)$, with the residue $r(j)$ which vanishes at $j = 0, -2, -4, \cdots$. Closing the contour first in the lower-half $\nu$-plane, (2.4) leads to a single-Mellin representation

$$F(u, v) \approx -\int \frac{dj}{2\pi i} \frac{1 + e^{-i\pi j}}{\sin \pi j} r(j) \sigma^{1-j} e^{(2-\Delta(j))\rho} \frac{\sinh \rho}{\sin \rho},$$

(2.6)

where we have taken the limit of $\sqrt{u} = \sigma$ small, with $(1 - v)/\sqrt{u} \approx 2 \cosh \rho$ fixed. In this limit, the dominant contribution comes from the right-most singularity in the $j$-plane, which enters through $\Delta(j)$. Consider next the spectral curve $\Delta(j)$ for Pomeron exchange and focus on the strong coupling limit where one has $\Delta(j) = 2 + \sqrt{2}\lambda^{1/4}\sqrt{j - j_0}$, with $j_0$ given by (1.1). Observe that this gives a fixed branch-cut in the $j$-plane. In the limit $\sigma \to 0$, by pushing the $j$-contour to the left and picking up the contribution from the branch-cut at $j = j_0$, (2.6) leads directly to the singular behavior (1.7), as promised. A similar result is also obtained if one considers the weak coupling expansion of the spectral curve $\Delta(j)$, but now $j_0$ in (1.7) is given by the BFKL expansion (1.2).

**AdS Impact parameter representation:** Now let us turn to a momentum space treatment for the Regge limit in CFT. Consider the Fourier transform of the connected correlation function defined in (1.4),

$$(2\pi)^4 \delta^{(4)} \left( \sum p_j \right) i T(p_1, p_2, p_3, p_4) = \langle O_1(p_1)O_2(p_2)O_3(p_3)O_4(p_4) \rangle_c .$$

(2.7)

The amplitude $T(p_j)$ can be expressed as a function of Mandelstam invariants $s$, $t$, and $p_j^2$. The Regge limit corresponds to $s$ large, which defines a light-cone direction, with $t < 0$ and $p_j^2$ fixed. In this limit, the momentum transfer is asymptotically transverse, with $t = (p_1 + p_2)^2 \approx -q_{\perp}^2$. Using conformal symmetry, it is possible to express the amplitude $T(p_j)$ in an AdS impact parameter representation, which in the Regge limit takes the form $[29, 30, 24, 25]

$$T(s, t, p_j^2) \approx \int \frac{dz}{z^5} \frac{dz'}{z'^5} \Phi_1(z, p_j^2)\Phi_2(z, p_j^2) \mathcal{G}(s, t, z, z') \Phi_3(z', p_j^2)\Phi_4(z', p_j^2),$$

(2.8)

$$\mathcal{G}(s, t, z, z') = (zz')^2 s \int \frac{d^2b_{\perp}}{4\pi^2} e^{iq_{\perp} \cdot b_{\perp}} T(S, L),$$

with $b_{\perp}$ the two-dimensional impact parameter introduced earlier (1.0). The amplitude $T = T(S, L)$ encodes all dynamical information and, due to conformal symmetry, depends only on the variables

$$S = zz' s, \quad \cosh L = \frac{z^2 + z'^2 + b_{\perp}^2}{2zz'}. $$

(2.9)

The same representation was obtained through direct AdS/CFT considerations $[5, 27, 28]$, via generalized Witten diagrams, string vertex operators, etc., leading to a Regge kernel, $\mathcal{K}(s, b_{\perp}, z, z')$. Up to irrelevant
constants, this kernel is related to the amplitude $\mathcal{T}(S, L)$ by

$$
\mathcal{K}(s, b_{\perp}, z, z') \sim N^2 (zz')^2 s \mathcal{T}(S, L).
$$

The Regge limit is now $S \to \infty$ with fixed $L$. It is important to note that the conformal representation (2.8) of the amplitude is valid for any value of the coupling constant, since it relies only on conformal invariance. However, it is quite natural from the view point of the dual $AdS$ scattering process, where transverse space is precisely a three-dimensional hyperbolic space $H_3$, whose boundary is conformal to the physical transverse space $\mathbb{R}^2$. The cross ratio $L$ is then identified with the geodesic distance between two points in $H_3$ that are separated by $b_{\perp}$ along $\mathbb{R}^2$ and have radial coordinates $z$ and $z'$. The other cross ratio $S = zz'$ measures the local energy squared of the scattering process in $AdS$, since $z$ and $z'$ define the local $AdS$ scales for each incoming particle. Moreover, the functions $\Phi_i(z, p_i^2)$ are $AdS$ bulk to boundary propagators with a plane wave source of momentum $p_i$ created by the gauge theory operator at the boundary $z \to 0$. To define on-shell scattering for non-conformal amplitudes, $T(s, t)$, as introduced in Ref. [5], one deforms the dual $AdS$ space in the IR, breaking conformal symmetry, and replaces $\Phi_i(z, p_i^2)$ by normalizable wave functions for “hadronic” (or glueball) eigenstates.

By considering the radial Fourier decomposition in the $AdS$ impact parameter space $H_3$, one can derive a double Mellin representation of the kernel, as done earlier for CFT analysis in a coordinate representation, Eq. (2.4). This radial decomposition simply considers harmonic functions $\Omega_{\iota \nu}$ on $H_3$, given by (2.3), which satisfy $(\nabla^2 + 1 + \nu^2) \Omega_{\iota \nu} = 0$, where $\nabla^2$ is the $H_3$ Laplacian. This is equivalent to introducing $\mathbb{R}^2$ harmonic functions, $e^{iq \cdot b_z}$, in the standard impact parameter decomposition. The only difference is that now we have a scattering process in $AdS$ space. From a CFT point of view, this representation can also be derived by writing the conformal partial wave decomposition of the amplitude $\mathcal{T}(S, L)$, and then taking the Regge limit. Thus, as before, the $\nu$-integral reflects conformal invariance due to dilatation, and the $j$-integral represents a coherent sum of $t$-channel spin fields, as was done earlier for the OPE sum via a Sommerfeld-Watson transform. To be more explicit, since the Pomeron/Odderon kernels receive contributions respectively from all even/odd spins, these kernels can be expressed as

$$
\mathcal{K}_\pm(s, b_{\perp}, z, z') = -(zz') \int \frac{dj}{2\pi i} \frac{1 \pm e^{-i\pi j}}{\sin \pi j} \int_{-\infty}^{\infty} \frac{d\nu}{2\pi} S^j G^\pm(j, \nu) \Omega_{\iota \nu}(L). 
$$

This representation is a consequence of conformal invariance, which must next be supplemented by dynamics, i.e., specifying the Pomeron/Odderon propagator $G(j, \nu)$.

By examining Witten diagrams for exchanging spin-$j$ fields in the Regge limit and also their string duals, one is led to $G(j, \nu)$ having a simple pole in the $\nu^2$-plane, determined by the spectral curve $\Delta(j)$ associated with these fields, exactly as in coordinate treatment (2.5). Here $G(j, \nu)$ can be related to the $\nu$-transform of a transverse scalar bulk-bulk propagator with an effective $j$-dependent $AdS$ mass. The residue at this pole can be related to the local $AdS$ coupling of the exchanged fields to the external states. Upon closing the $\nu$-contour, one picks up a factor $G(j, b_{\perp}, z, z') \sim e^{-(\Delta(j)-2)L}/\sinh L$.

\footnote{The $1/N^2$ dependence in $\mathcal{T}(S, L)$, expected for $AdS$ gravitational interactions, is normally removed from $\mathcal{K}$. In [27, 28], a reduced variable $\bar{s} = S = zz's$ was used extensively. One occasionally also used $\eta$ or $\xi$, instead of $L$.}

\footnote{Note that at weak coupling the product of wave functions $\Phi_1 \Phi_2$ and $\Phi_3 \Phi_4$ are similarly replaced by the dipole parton distributions for the external particles [28], so that this impact parameter representation [28] is maintained.}
Finally, for Pomeron(Odderon) exchange, by identifying the $j$-plane branch-point at $j_0$ associated with the Pomeron(Odderon) spectral curve, from (2.11) one has for $S$ large, by pulling the contour to the left,

$$K(s, b^2_1, z, z') \simeq (zz') f(L) \frac{S^{j_0}}{\ln S^{3/2}},$$

(2.12)

just as in the coordinate representation (1.7).

**Regge Dictionary for CFT:** We have therefore two representations of the correlation function in the Regge limit. One derived from the CFT analysis in position space $F(u, v)$, given by (2.4), and another from a computation in momentum space with a clear geometrical interpretation as a scattering process in $AdS$, given by (2.11). This establishes a dictionary, where, in the Regge limit,

$$F(u, v) \leftrightarrow T(S, L) = N^{-2} (zz')^{-2} s^{-1} K(s, b^2_1, z, z'),$$

$$\sigma = \sqrt{u} \leftrightarrow S^{-1} = (zz's)^{-1},$$

$$\cosh \rho \approx \frac{1 - v}{2\sqrt{u}} \leftrightarrow \cosh L = \frac{b^2_1 + z^2 + z'^2}{2zz'}.$$  

(2.13)

Although it is possible to carry out a more formal analysis in establishing this equivalence, we will not pursue this here [26]. It suffices to emphasize the exact equivalence of the two approaches to identify the spectral curve, $\Delta(j)$ in Fig. 1, which serves as the common link between them.

### 3 Conformal Pomeron

The Pomeron spectral curve $\Delta_P(j)$ in the strong coupling limit, Fig. 1 can be obtained by an intuitive derivation based on a flat-space leading closed-string linear trajectory. Through AdS/CFT, this simple result can be understood as a perturbation about the traceless-transverse graviton mode, $\nabla^2 h_{MN} = 0$, with $j = 2$ and $\Delta = 4$ in the $\lambda = \infty$ super-gravity limit. Here $\nabla^2$ is the tensor Laplacian on $AdS_5$. Let us now consider the limit of $j \to 2$ and $\lambda \to \infty$ with $\sqrt{\lambda}(j - 2)$ fixed. This limit can be understood by introducing a Reggeon vertex operator, $V^{\pm}$, on the string world sheet in a weakly curved target $AdS_5 \times S^5$ space [5]. This Reggeon vertex operator depends on $(j, \nu, t)$ for the $O(4,2)$ Casimir, and on $k = \tau - 2$ in case we wish to consider exchange of $SO(6)$ $R$-charge. The effect of the Reggeon operator is to resum the exchange of all modes in the leading Regge trajectory with even positive integral spins, which leads to the effective Regge spin

$$j = 2 - \frac{\tau^2 + \nu^2}{2\sqrt{\lambda}}.$$  

(3.1)

Then the world-sheet Virasoro on-shell condition, $L_0 V^{\pm} = \bar{L}_0 V^{\pm} = \nu^{\pm}$, establishes the relation

$$\Delta_P(j, \tau) = 2 + i\nu$$  

(3.2)

where $\Delta_P(j, \tau)$ is the continuation of the anomalous dimension curve for the exchanged gauge theory operators in the leading Regge trajectory $O^{\pm}_{\rho}(j, \tau)$ given in [18]. By following this procedure, one relates the exchange of $AdS$ higher spin fields to the dual gauge theory operators with spectral curve $\Delta_P(j, \tau).$
In the above double limit the Regge spin has a quadratic dependence in the dimension $\nu$, also known as the diffusion limit (in a weak coupling expansion we may also consider such a diffusion limit). The terminology stems from the fact that the kernel in momentum space takes on a diffusion form at $t = 0$, with diffusion time $\ln(z'z)$ fixed by the AdS energy $S = zz'$ \cite{5}. In this limit we can already observe that the spectral curve $\Delta_P(j, \tau)$ has a branch point at $j_0$,

$$\Delta_P(j) = 2 + \sqrt{2\lambda^{1/2}} j - j_0 .$$  \hspace{1cm} (3.3)

where

$$j_0 = 2 \frac{\tau^2}{2\sqrt{\lambda}} ,$$  \hspace{1cm} (3.4)

which generalizes (1.1) for the case of twist $\tau$.

Beyond the diffusion limit (3.1) the Reggeon spin $j = j(\nu, \tau)$ admits the strong coupling expansion

$$j(\nu, \tau) = 2 - \tau^2 + \nu^2 \frac{2\sqrt{\lambda}}{2\sqrt{\lambda}} \left( 1 + \sum_{n=2}^{\infty} \frac{j_n(\nu^2, \tau)}{\lambda^{(n-1)/2}} \right) ,$$  \hspace{1cm} (3.5)

which is a simple generalisation to arbitrary twist $\tau$ of the results presented in \cite{24,16} (such that at infinite coupling, for $j = 2$, the dimension of the operator is given by the protected value of $2 + \tau$). Notice that $j(\nu, \tau)$ must be an even function of $\nu$ to implement the symmetry property $\Delta_P(j, \tau) \leftrightarrow 4 - \Delta_P(j, \tau)$. The function $\tilde{j}_n(\nu^2, \tau)$, defined for $n \geq 2$, is a polynomial of degree $n - 2$,

$$\tilde{j}_n(\nu^2, \tau) = \sum_{k=0}^{n-2} c_{n,k} \nu^{2k} ,$$  \hspace{1cm} (3.6)

with $\tau$-dependent coefficients $c_{n,k}$. This follows from the requirement that the AdS amplitude has a well defined flat space limit \cite{24}. Consistency with the strong coupling expansion of the spectral curve $\Delta_P(j, \tau)$ further restricts this polynomials to have smaller degree \cite{16}, more precisely, for $n \geq 4$

$$c_{n,k} = 0 \text{ for } \left[ \frac{n}{2} \right] \leq k \leq n - 2 ,$$  \hspace{1cm} (3.7)

as also confirmed in \cite{18}.

Eq. (3.5) corresponds to an expansion for the Reggeon spin about the symmetry point $\Delta = 2$, ($\nu^2 = 0)$, in the strong coupling limit, subject to the constraint that $j = 2$ at $\nu^2 = -\tau^2$. In the next subsection we review recent results for the strong coupling expansion of the spectral curve $\Delta_P(j, \tau)$ about $j = 2$ that will allow us to compute the pomeron spin $j(\nu)$, i.e., the inverse of the spectral curve $\Delta(j)$, with $\Delta$ and $\nu$ related by (3.2), beyond the diffusion limit at arbitrary twist $\tau$. The discussion leads to a unified picture that can also be applied to the Odderon Regge trajectories, in Sec. 4.

### 3.1 Pomeron spin versus anomalous dimensions at strong coupling

Much attention has been paid in recent years to the study of anomalous dimensions for composite operators of $\mathcal{N} = 4$ SYM. Because of supersymmetry, many related operators share the same anomalous
dimensions. It is generally believed that, due to integrability \[34\], scaling dimensions for gauge invariant operators can be efficiently calculated for all 't Hooft coupling, in the large-\(N\) planar limit, via the so-called TBA/Y-system and its generalizations \[34\]. These operators and their cousins can be treated as generalized Heisenberg spin chains. For instance, the weak-coupling one-loop anomalous dimension \(\gamma(S, \tau)\) of single-trace operators in the \(sl(2)\) sector, symbolically expressed as \(Tr[D^2_{\pm} Z^\tau] + \cdots\), can be calculated explicitly, with \(\Delta(S, \tau) = S + \tau + \gamma(S, \tau)\) their scaling dimension. However, beyond one-loop, and particularly for short operators (\(S\) and \(\tau\) small), analytic solutions have been difficult to obtain. For strong coupling, conformal dimensions can be calculated semi-classically in a world-sheet sigma model approach around soliton solutions \[35, 36, 37\], as semi-classical treatment for GKP strings. This leads to a strong coupling loop-expansion, with 1-loop contribution around soliton solutions \[35, 36, 37\], as semi-classical treatment for GKP strings. This leads to a strong coupling loop-expansion, with 1/\(\sqrt{X}\) playing the role of \(\hbar\),

\[
\Delta = \lambda^{1/4} \left( \delta_0 + \frac{\delta_1}{\lambda^{1/2}} + \frac{\delta_2}{\lambda} + \frac{\delta_3}{\lambda^{3/2}} + \frac{\delta_4}{\lambda^2} + \cdots \right),
\]

(3.8)

with \(S\) and \(\tau\) dependence entering the \(\ell\)-loop contribution \(\delta_\ell\) through a scaling hypothesis. However, calculation beyond 1-loop is impractical. In most approaches of this type, the emphasis has been on long strings.

One analysis of particular interest to us is the expansion for the spectral curve about the point \(S = 0\),

\[
\Delta_Z(S, \tau) = \tau + \alpha_1(\tau, \lambda)S + \alpha_2(\tau, \lambda)S^2 + \alpha_3(\tau, \lambda)S^3 + \cdots
\]

(3.9)

where \(\Delta_Z(0, \tau) = \tau\), since the operator is 1/2-BPS and its dimension is protected. The form of the “slope function”, \(\alpha_1(\lambda, \tau)\), has recently been conjectured by Basso for all 't Hooft coupling \[15\] (see also \[40, 41\]), which can be expressed in a compact form in terms of Bessel functions,

\[
\alpha_1(\lambda, \tau) = \frac{\sqrt{\lambda}}{\tau} Y_\tau(\sqrt{\lambda}),
\]

(3.10)

for all \(\tau\), with \(Y_\tau(x) = I_\tau(x)/I_\tau(x)\), where \(I_\tau(x)\) is the \(\tau\)-th modified bessel function. At weak coupling, \(\alpha_1(\lambda, \tau) = 1 + O(\lambda)\), and at the strong coupling, \(\alpha_1(\lambda, \tau) = \sqrt{\lambda}/\tau + O(1/\sqrt{\lambda})\). This result was first derived for \(\tau = 2\) as a solution to the “asymptotic Bethe ansatz” (ABA) equations. It has been argued in \[15\], with further support in \[40, 41\], that this holds for all \(\tau > 2\), for the configurations with “minimum mode numbers”. More recently, the second coefficient, \(\alpha_2(\lambda, \tau)\), has also been calculated numerically, but it is not possible at this moment to express it in a closed form in terms of elementary functions \[40, 41\].

Due to super-symmetry, it is known that the Pomeron spectral curve \[3\] is directly related to \(\Delta_Z(S, \tau)\) at \(\tau = 2\) by \[22, 23\]

\[
\Delta_P(j) = 2 + \Delta_Z(j - 2, 2).
\]

(3.11)

Therefore, these recent analyses, appropriately generalized, can be applied to our study of conformal Pomeron and Odderon, particularly in the large \(\lambda\) limit.

---

\[\text{\[3\]}\] \(\delta_\ell\) is assumed to be a function of \(S = S/\sqrt{X}\) and \(T = T/\sqrt{X}\). Occasional discussions for small \(S\) and/or small \(T\) are typically based on extrapolation under this scaling hypothesis. As such, less attention has been paid in the past to the symmetry property in \(\Delta\). For an alternative but related study, see \[45, 49\].

\[\text{\[4\]}\] We will return to a discussion on this and related issues in Secs. \[4\] and \[4\].

\[\text{\[5\]}\] In order to avoid notational confusion, in what follows, instead of \(S\), we shall switch to \(j = S + 2\), e.g., for the \(sl(2)\) sector, we have \(Tr[D_{\pm}^{j - 2} Z^\tau]\), instead of \(Tr[D_{\pm}^{S} Z^\tau]\).
For planar $\mathcal{N} = 4$ SYM, it is possible to generalize our discussion for the Pomeron spectral curve to include CFT operators with $R$ charges, which through AdS/CFT, amounts to allow fluctuations in $S^5$. For our purpose, as already described in [13], the relevant CFT operators are

$$O_P(j, \tau) = Tr[F_{\mu\sigma} D_{\rho_1} \cdots D_{\rho_s} F_{\sigma\nu} Z^{\tau-2}] + \cdots,$$

(3.12)

with $\tau = 2 + k \geq 2$. For the leading Regge singularity, we will be dealing with the light-cone components $Tr[F_{\pm\pm} D_{\pm} \cdots D_{\pm} F_{\pm\pm} Z^{\tau-2}] + \cdots$. The generalized Pomeron spectral curve $\Delta_P(j, \tau)$ can be expanded using (3.11) and (3.13) around $j = 2$, leading to

$$\Delta_P(j, \tau) = 2 + \tau + \alpha_1(\lambda, \tau)(j-2) + \alpha_2(\lambda, \tau)(j-2)^2 + \alpha_3(\lambda, \tau)(j-2)^3 + \cdots.$$  

(3.13)

where (3.10) applies.

Because of the symmetry under $\Delta_P(j, \tau) \leftrightarrow 4 - \Delta_P(j, \tau)$, we again require the function $\Delta_P(j, \tau)$ to have a square-root singularity at $j_0(\tau)$, with $j_0(\tau) = 2 - O(\lambda^{-1/2})$. This branch point renders the expansion (3.13) with a radius of convergence which vanishes as $\lambda^{-1/2}$, leading to expansion coefficients which grow as $\alpha_n \sim O(\lambda^{n/2})$. Nevertheless, a convergent expansion can be achieved by considering the symmetric combination $(\Delta_P(j, \tau) - 2)^2 = -\nu^2$, for which this square-root branch point is absent. This in turn leads to a convergent expansion in the strong coupling limit,

$$(\Delta_P(j, \tau) - 2)^2 = \tau^2 + \beta_1(\lambda, \tau)(j-2) + \beta_2(\lambda, \tau)(j-2)^2 + \beta_3(\lambda, \tau)(j-2)^3 + \cdots,$$

(3.14)

where $\beta_1(\lambda, \tau) = 2\tau \alpha_1(\lambda, \tau)$, $\beta_2(\lambda, \tau) = \alpha_1(\lambda, \tau)^2 + 2\tau^2 \alpha_2(\lambda, \tau)$, etc. Based partly on semi-classical analysis of GKP strings [35, 36, 37], one expects a radius of convergence of the order $O(\lambda^{1/2})$. Consistency with (3.8) and the existence of a smooth super-gravity limit then require that $\beta_n \sim O(\lambda^{(2-n)/2})$, so that each coefficient $\beta_n(\lambda)$ in turn admits an expansion,

$$\beta_n = 2\lambda^{2-n} \left( b_{n,0} + b_{n,1} \lambda^{1/2} + b_{n,2} \lambda^{3/2} + \cdots \right),$$

(3.15)

where we have taken the factor of 2 out so that later on the expansion will be normalized with $b_{1,0} = 1$, and the coefficients $b_{n,m}$ are in general $\tau$-dependent. The viability of the strong coupling treatment done by Basso in [15] relies on this rapidly convergent expansion [10]. It is now a simple exercise to check that, since $\beta_n$ starts at order $\lambda^{(2-n)/2}$, we have

$$(\Delta_P(j, \tau) - 2)^2 = \tau^2 + 2\sqrt{\lambda}(j-2) \left( 1 + \sum_{k=1}^{\infty} \lambda^{-k/2} \frac{H_k(j-2, \tau)}{\lambda^k} \right),$$

(3.16)

with

$$H_k(j-2, \tau) = \sum_{n=0}^{k} b_{n+1,k-n}(j-2)^n.$$  

(3.17)

a polynomial of degree $k$ in $(j-2)$. The form of this expansion should be compared with (3.5) for the function $j(\nu, \tau)$. Both expansions make explicit that we are doing a strong coupling expansion around the diffusion limit $j \to 2$ and $\lambda \to \infty$ with $\sqrt{\lambda}(j-2)$ fixed.

---

10It is worth noting that the expansion for $\beta_1$ in $1/\sqrt{\lambda}$ can be identified with the GKP-loop expansion, i.e., the coefficient $b_{1,1}$ is a $m$-loop contribution. The same no longer holds for $\beta_n, n > 1$. In general, each coefficient $b_{n,m}$ mixes contributions from different loop orders.
Let us now relate the expansions (3.14) and (3.10) for the dimension $\Delta_P(j, \tau)$, to the expansion (3.15) for the Reggeon spin $j(\nu, \tau)$. For simplicity we consider first the computation of the intercept. Since $\beta_1(\lambda, \tau) > 0$ the function $j(\nu, \tau)$ has a minimum at $\nu = 0$ ($\Delta = 2$). This minimum determines the Pomeron intercept $j_0 = j(0, \tau)$. Thus, setting $\Delta_P(j_0, \tau) = 2$ in (3.14) we learn that the intercept is fixed by
\[
0 = (\Delta_P(j_0, \tau) - 2)^2 = \tau^2 + \beta_1(\lambda, \tau)(j_0 - 2) + \beta_2(\lambda, \tau)(j_0 - 2)^2 + \beta_3(\lambda, \tau)(j_0 - 2)^3 + \cdots ,
\]
with $\beta_n$ given by the expansion (3.15). Replacing the expansion for the intercept, as defined by (3.5), it is now possible to find $j_0$ iteratively in an expansion
\[
j_0 = 2 + \frac{c_1}{\lambda^{1/2}} + \frac{c_2}{\lambda^{1/2}} + \frac{c_3}{\lambda^{3/2}} + \frac{c_4}{\lambda^2} + \cdots.
\]
Note that the coefficients $c_i$ are already defined in the expansion (3.5) of the Reggeon spin function, more precisely we have $c_1 = -\tau^2/2$ and $c_n = c_1 c_{n,0}$ for $n \geq 2$. Substituting (3.19) and (3.15) into (3.18), and collecting all terms in powers of $1/\sqrt{\lambda}$, one can determine $c_n$ iteratively. To illustrate how this goes, we list here the first few coefficients (note that we set $b_{10} = 1$),

\[
\begin{align*}
c_1 &= -\tau^2/2, \\
c_2 &= -b_{1,1} c_1, \\
c_3 &= -[b_{1,1} c_2 + b_{1,2} c_1 + b_{2,0} c_2^2], \\
c_4 &= -[b_{1,1} c_3 + b_{1,2} c_2 + b_{1,3} c_1 + 2b_{2,0} c_1 c_2 + b_{2,1} c_2^2], \\
c_5 &= -[b_{1,1} c_4 + b_{1,2} c_3 + b_{1,3} c_2 + b_{1,4} c_1 + 2b_{2,0} c_1 c_2 + b_{2,1} c_1 c_2 + b_{2,2} c_2^2 + b_{3,0} c_3^2], \\
c_6 &= -[b_{3,1} c_1^3 + b_{3,2} c_1^2 + b_{3,3} c_2 c_1^2 + b_{1,5} c_1 + 2b_{2,2} c_2 c_1 + 2b_{2,1} c_3 c_1 + 2b_{2,0} c_1 c_4 + b_{2,1} c_2^3 + b_{1,4} c_2 + b_{1,3} c_3 + 2b_{2,0} c_2 c_3 + b_{1,2} c_4 + b_{1,1} c_5].
\end{align*}
\]

In the diffusion limit, the intercept reduces to $\alpha_P(\tau) \equiv j_0(\tau) = 2 - \tau^2/2\sqrt{\lambda}$, as stated above. As for the leading twist case, $\tau = 2$, this intercept corresponds to the location of a square-root branch point for the spectral curve $\Delta_P(j, \tau)$, and it approaches $j = 2$ in the limit of $\lambda \to \infty$.

More generally, we can relate the coefficients of the polynomials $H_k(j - 2, \tau)$ entering the expansion (3.16) of $\Delta_P(j, \tau)$, with the coefficients of the polynomials $\hat{j}_n(\nu^2, \tau)$ entering the expansion (3.5) of $j(\nu, \tau)$. These functions are simply related by the inversion formula $\Delta_P(j(\nu, \tau), \tau) = 2 + i\nu$ given in (3.2). This is a mechanical computation, so we only give here the relation between the first coefficients without further explanations (excluding the coefficients $c_{n,0}$ already given above)

\[
\begin{align*}
c_{3,1} &= b_{2,0}/2, & c_{4,1} &= \left[-3b_{1,1} b_{2,0} + b_{2,1}\right]/2, & c_{4,2} &= 0, \\
c_{5,1} &= \left[6b_{1,1}^2 b_{2,0} - 3b_{1,2} b_{2,0} + 2\tau^2 b_{2,0} - 3b_{1,1} b_{2,1} + b_{2,2} - \tau^2 b_{3,0}\right]/2, \\
c_{5,2} &= \left[2b_{2,0}^2 - b_{3,0}\right]/4, & c_{5,3} &= 0, \\
c_{6,1} &= \left[-10b_{1,1}^3 b_{2,0} + 12b_{1,1} b_{1,2} b_{2,0} - 3b_{1,3} b_{2,0} - 10\tau^2 b_{1,1} b_{2,0}^2 + 6b_{1,1}^2 b_{2,0} + 6b_{1,1}^2 b_{2,1} - 3b_{1,2} b_{2,1} + 4\tau^2 b_{2,0} b_{2,1} - 3b_{1,1} b_{2,2} + b_{2,3} + 4\tau^2 b_{1,1} b_{2,1} - \tau^2 b_{3,1}\right]/2, \\
c_{6,2} &= \left[-10b_{1,1}^2 b_{2,0} + 4b_{2,0} b_{2,1} + 4b_{1,1} b_{3,0} - b_{3,1}\right]/4, & c_{6,3} &= c_{6,4} &= 0.
\end{align*}
\]
3.2 Explicit results for $\mathcal{N} = 4$ SYM

It is now clear that we can use the known results for the spectral curve $\Delta_P(j, \tau)$ for $j \sim 2$ to extract information about the strong coupling expansion Pomeron spin $j(\nu, \tau)$, and in particular to compute the Pomeron intercept for $\tau \geq 2$. We begin by noting that, since $\beta_1(\lambda, \tau) = 2\tau\alpha_1(\lambda, \tau)$ is known analytically, it can be easily expanded in powers of $1/\sqrt{\lambda}$, with the result $^{13}$

$$
\beta_1(\lambda, \tau) = 2\lambda^{1/2} \left(1 - \frac{1}{2\lambda^{1/2}} + \frac{4\tau^2 - 1}{8\lambda} + \frac{4\tau^2 - 1}{8\lambda^{3/2}} + \frac{-16\tau^4 + 104\tau^2 - 25}{128\lambda^2} + \frac{-16\tau^4 + 56\tau^2 - 13}{32\lambda^{5/2}} + \cdots \right). \tag{3.22}
$$

From this expansion it is straightforward to extract the coefficients $b_{1,m}$. This is enough to fix $c_1$ and $c_2$ in the computation of the intercept $^{1}$, and in particular agrees with the diffusion limit result $\nu_0 = -\sqrt{\lambda}/2$. $^{11}$

To find the intercept coefficients $c_n$ for $n > 2$, knowledge of the coefficients $b_{n,m}$ for higher $\beta_n$ are required. As mentioned earlier, $^{3,13}$ is an expansion with increasingly divergent coefficients, i.e. $\alpha_n = O(\lambda^{n/2})$. Clearly, very special cancellations must take place in moving from $^{3.13}$ to $^{3.14}$ for convergence. Recently, explicit expressions for $\alpha_2(\lambda, \tau)$, $\tau = 2$ and 3, have been obtained $^{19}$. With the aid of numerical analysis, together with consistency matching with $^{3.22}$, $^{19}$ also gives strong coupling expansions for arbitrary $\tau$, up to order $\lambda^{-3/2}$,

$$
\alpha_2(\lambda, \tau) = \frac{\lambda}{2\tau^3} + \frac{\lambda^{1/2}}{2\tau^3} + \frac{1}{4\tau} + \frac{1 - \tau^2(24\zeta(3) + 1)}{16\tau^3\lambda^{1/2}} - \frac{8\tau^4 + \tau^2(72\zeta(3) + 11) - 4}{32\tau^3\lambda} + \frac{24\tau^4(16\zeta(3) + 20\zeta(5) - 7) - 48\tau^2(31\zeta(3) + 20\zeta(5) + 7) + 75}{256\tau^3\lambda^{3/2}} + O(\lambda^{-2}). \tag{3.23}
$$

It is then possible to calculate expansions for $\beta_2$, with relevant low order coefficients $b_{2,m}$ extracted from the expansions of $\alpha_1$ and $\alpha_2$,

$$
\beta_2(\lambda, \tau) = 2 \left(3 - \frac{3\zeta(3) - 3/8}{2\lambda^{1/2}} - \frac{\tau^2 + 9\zeta(3) - 5/8}{4\lambda^{3/2}} + \frac{\tau^2(3\zeta(3) + 15\zeta(5)/4 - 27/16 - 15\zeta(5)/2 - 93\zeta(3)/8 - 3/16}{2\lambda^2} + \cdots \right). \tag{3.24}
$$

The expansions of $\beta_n$ for $n > 2$ are currently not known to high order. However, as discussed in section 6.3 of $^{19}$, from an analysis of classical energy, with semi-classical corrections, it is in principle possible to extract the $\tau$-independent coefficients $b_{n,0}$ and $b_{n,1}$ for all $n$. For our calculation of the intercepts we use $b_{3,0} = -3/16$ and $b_{3,1} = (60\zeta(3) + 60\zeta(5) - 17)/32$. Note that all coefficients $b_{n,m}$ are polynomials in $\tau$, regular at $\tau = 0$. We have also identified, for each coefficient, its order in a string loop-expansion $^{33, 36, 37}$. With these coefficients it is possible to fix the $c_n$ up to $n = 6$. Thus, from $^{13}$The all coupling expansion carries more information about the coefficients $c_{n,k}$ of the $j(\nu, \tau)$ expansion $^{35}$. Indeed, it is simple to check that the combination $\sum_{k=0}^{n-2}(-1)^k\tau^2k\cdot c_{n,k}$ is entirely fixed by the coefficients $b_{1,m}$ with $m < n$. 

13
In Section, we examine these strong coupling results, exactly at growth, the 't Hooft coupling \([50]\). It has also been suggested recently, for \(N\) allowed asymptotic term consistent with saturating the Froissart unitarity bound. A more thorough discussion can be found in \([20]\) and references therein.

\[3.20\), we find that the generalized Pomeron intercept is given by

\[
\alpha_P(\lambda, \tau) = j_0(\lambda, \tau) = 2 - \frac{\tau^2}{2\lambda^{1/2}} + \frac{\tau^2}{4\lambda} + \frac{\tau^2(-3 + \tau^2)}{16\lambda^{3/2}} - \frac{\tau^2[-12 + \tau^2(11 + 24\zeta(3))]}{64\lambda^2} \\
+ \frac{\tau^2[63 + 6\tau^2(19 + 48\zeta(3)) - 2\tau^4]}{256\lambda^{5/2}} \\
+ \frac{\tau^2[-216 + \tau^2(637 + 1536\zeta(3) + 480\zeta(5)) - 2\tau^4(17 + 36\zeta(3) + 60\zeta(5))]}{512\lambda^3} + \ldots.
\]

(3.25)

For \(\tau = 2\) notice that the \(\zeta(5)\) term is absent from \(c_6\) due to cancellation, but it is in general present. We will show in the next section that just by varying \(\tau\), we can use this equation to calculate the Odderon intercept to the same order as above.

We may also compute, with the above information, the remaining coefficients \(c_{n,k}\) up to \(n = 6\), by using \([3.21]\). Such non-vanishing coefficients are \([12]\)

\[
c_{3,1} = \frac{3}{8}, \quad c_{4,1} = \frac{3}{32} \left[ 7 - 8\zeta(3) \right], \quad c_{5,1} = \frac{59 - 144\zeta(3) - 2\tau^2}{64}, \quad c_{5,2} = \frac{21}{64}, \\
c_{6,1} = \frac{291 - 480\zeta(5) - 76\tau^2 - 48\zeta(3)(32 + 7\tau^2)}{256}, \quad c_{6,2} = \frac{137 - 204\zeta(3) - 60\zeta(5)}{128}.
\]

(3.26)

\section{Conformal Odderon}

It is appropriate to begin by first mentioning that the importance of Pomeron lies partly in the fact that all high energy hadron-hadron total cross sections \(\sigma_T\) continue to rise from collider to cosmic ray energies. This universal behavior can be understood as driven initially by the leading \(1/N_c\) power law growth, \(\sigma_T \sim s^{\alpha_p-1}\) for the Pomeron intercept \(\alpha_p > 1\). Eventually agreement with the Froissart bound \(\sigma_T \sim \log^2 s\) requires a re-summation of higher order terms in \(1/N_c^2\) expansion \([13]\). The importance of the leading \(C = -1\) component, generically referred to as the Odderon \([43, 44, 45, 46]\), lies in the fact that it contributes to the difference of the antiparticle-particle and particle-particle total cross sections, \(\Delta \sigma_T(s) \sim s^{\alpha_o-1}\).

In the weak coupling limit, the Pomeron \([7, 8, 9, 10, 11]\) can be associated with 2-gluon exchange whereas Odderon can be thought as a \(C = -1\) composite of a three-gluon system \([7, 15, 16, 50, 51, 52, 53]\). Two leading Odderon have been identified. One has an intercept slightly below one \([47, 48, 49]\), with \(\alpha_{O,a} \simeq 1 - O(\lambda)\), and the second has an intercept exactly at one, \(\alpha_{O,b} \simeq 1\), up to third order in the 't Hooft coupling \([50]\). It has also been suggested recently, for \(N = 4\) SYM, that the latter remains exactly at \(j = 1\), to all orders in weak coupling, \([51, 52]\). Interestingly, these correspond nicely with strong coupling analysis in the diffusion limit \([20, 56]\). In this Section, we examine these strong coupling results,

\[\text{Actually, since } [12] \text{ also computes } b_{4,0} = 31/128 \text{ and } b_{4,1} = (901 - 5520\zeta(3) - 5120\zeta(5) - 3640\zeta(7))/1024, \text{ we can determine } c_{7,3} = 391/1024 \text{ and } c_{8,4} = (15081 - 27120\zeta(3) - 12320\zeta(5) - 3640\zeta(7))/8192.
\]

\[\text{One often adopts an eikonal sum. Alternatively, the data is sometimes fitted directly by } \sigma_T \sim \log^2 s, \text{ the maximally allowed asymptotic term consistent with saturating the Froissart unitarity bound. A more thorough discussion can be found in } [20] \text{ and references therein.}\]
going beyond the diffusion limit. In particular, we clarify how for the special Odderon solution, \( \alpha_{O,b} = 1 \) at \( k = 0 \), can hold to all order in \( 1/\sqrt{\lambda} \).

For the Odderon, the large \( \lambda \) diffusion limit corresponds to setting \( \lambda \to \infty \) and \( j \to 1 \), with \( \sqrt{\lambda}(j-1) \) fixed. In this limit the Odderon propagator can be obtained by perturbing about the EOM for the anti-symmetric Kalb-Ramond field, \( B_{MN} \) in \( AdS \): \(-\Box_{\text{Maxwell}} + m_{\text{AdS}}^2)B_{MN} = 0 \). Here \( \Box_{\text{Maxwell}} \) stands for the Maxwell operator. Its exact form can be found in [20], and it can again be diagonalized in terms of \( O(4,2) \) Casimir. The result is that all modes with odd positive integral \( j \) contribute to the exchange, and one arrives at an effective propagator in the \( \nu^2 - j \) plane of the form

\[
G_O(j, \nu) \sim \frac{1}{\nu^2 + m_{\text{AdS}}^2 + 2\sqrt{\lambda}(j-1)}.
\]

As for the Pomeron, the relevant string modes can be represented by on-shell world-sheet Reggeon vertex operators \( V_O^\pm \) in \( AdS \). The on-shell condition, \( L_0 V_O^\pm = \overline{L}_0 V_O^\pm = V_O^\pm \), in analogy with (3.2), leads to \( \Delta_O(j) = 2 + i\nu \). It follows that the Odderon spectral curve in the strong coupling diffusion limit, given by the pole locations of \( G_O(j, \nu) \), is

\[
(\Delta_O(j) - 2)^2 = m_{\text{AdS}}^2 + 2\sqrt{\lambda}(j-1).
\]

Denoting \( \alpha_O(\lambda) \) for the Odderon intercept, it follows that

\[
\Delta_O(j) = 2 + \sqrt{2\lambda^{1/4}\sqrt{j - \alpha_O}},
\]

where in the diffusion limit

\[
\alpha_O(\lambda) = 1 - \frac{m_{\text{AdS},a}^2}{2\sqrt{\lambda}}.
\]

We also stress that because of super-symmetry the anomalous dimension at \( j = 1 \) is zero, more precisely, \( \Delta_O(1) = 2 + m_{\text{AdS}} \), for any value of the coupling. In the diffusion limit, the spectral curve \( \Delta_O(j) \) is again parabolic.

From the perspective of OPE, at \( j = 1 \), there are two sets of conformal primaries, each indexed by
integer \( k \), with protected conformal dimensions\(^\text{14}\).

\[
\Delta_{O}^{(a)}(1) = 2 + \tau_a = 2 + m_{AdS,a} = 6 + k,  
\Delta_{O}^{(b)}(1) = 2 + \tau_b = 2 + m_{AdS,b} = 2 + k.  
\]

Candidate dual CFT operators dual to these protected string modes are \( Tr(F_{\pm}Z^k) + \cdots \) and \( Tr(F_{\pm}Z^k) \), respectively. As usual, one expects that higher spin operators in the leading Regge trajectory can be obtained by acting with derivatives \( D^\pm \), leading to operator dimensions \( \Delta_{O}^{(a)}(2n+1) \) and \( \Delta_{O}^{(b)}(2n+1) \) respectively, at \( j = 2n+1, n = 1,2,\cdots \). However, these can only be obtained meaningfully beyond the diffusion limit.

### 4.1 Odderon Intercepts in Strong Coupling

To go beyond the diffusion limit, let us return to (3.14). In analogy to that equation and (3.16), we expand \( \Delta_{O}(j,\tau) - 2 \) about \( j = 1 \),

\[
(\Delta_{O}(j,\tau) - 2)^2 = \tau_2^2 + \beta_1^{(-)}(j-1) + \beta_2^{(-)}(j-1)^2 + \beta_3^{(-)}(j-1)^3 + \cdots.  
\]

We have also added a superscript to the expansion coefficients, \( \beta_n^{(-)} \), to remind ourselves that we are dealing with the \( C = -1 \) sector. Recall that (4.8) properly reflects the symmetry in \( \Delta_{O} \leftrightarrow 4 - \Delta_{O} \). To match the diffusion limit, we require

\[
\beta_1^{(-)}(\lambda,\tau_O) = 2\sqrt{\lambda} + O(1).  
\]

As is the case with the Pomeron, \( j(\Delta_{O}) \) has a minimum at \( \Delta_{O}(\alpha_O,\tau) = 2 \), which defines the Odderon intercept. This, of course, is also equivalent to the existence a square-root singularity, \( 4.3 \). We further assume that, as the case for the Pomeron, in the strong coupling limit, the radius of convergence for (4.8) is \( O(\lambda^{1/2}) \), and, \( \beta_n^{(-)} = O(\lambda^{(2-n)/2}) \). Correspondingly, we can develop a systematic expansion for \( \beta_n^{(-)}(\lambda) \) in \( 1/\sqrt{\lambda} \),

\[
\beta_n^{(-)} = 2\lambda^{3/2} \left( b_n^{(-)} + \frac{b_{n,1}^{(-)}}{\lambda^{1/2}} + \frac{b_{n,2}^{(-)}}{\lambda^{3/2}} + \frac{b_{n,3}^{(-)}}{\lambda^{5/2}} + \cdots \right).  
\]

We are now in the position to carry out a similar analysis for Odderon intercepts beyond the diffusion limit. Consider the expansion for the intercept

\[
\alpha_0(\lambda) = 1 + c_1^{(-)} + \frac{c_2^{(-)}}{\lambda} + \frac{c_3^{(-)}}{\lambda^{3/2}} + \frac{c_4^{(-)}}{\lambda^2} + \frac{c_5^{(-)}}{\lambda^{5/2}} + \cdots.  
\]

The coefficients in this expansion can be found by solving \( \Delta_{O}(\alpha_O,\tau) = 2 \) iteratively. Observe that the situation in nearly identical to that for the Pomeron. It follows that \( c_i^{(-)} \) are given exactly by the corresponding coefficients \( c_i \) for the Pomeron intercept, Eq. (3.20), with the replacements of \( \tau \) by \( m_{AdS} \), \( c_i \) by \( c_i^{(-)} \) and \( b_{n,1} \) by \( b_{n,1}^{(-)} \). For simplicity, we shall drop the superscript in what follows.

\(^{14}\)Of course, each contributes only to correlation functions with appropriate R-charge.
In the diffusion limit, our two sets of Odderon solutions are structurally similar. However, there is no particular reason why these two sets remain similar in higher orders and we shall treat them separately in what follows. We shall first consider type-(a), characterized by $\tau_a = m_{AdS} = 4 + k$, $k = 0, 1, 2, \cdots$, before treating the case for type-(b). It is worth mentioning again that the all-coupling formula (3.10) was derived from ABA equations, without the so-called wrapping corrections. It is surprising that they do not appear in the present context as one would expect them especially in the small spin limit. The physical motivation for their absence is not fully understood. Furthermore, it is supposed to hold only for the $sl(2)$ sector for the configuration with “minimum mode numbers”, which should correspond to the spectral curve with minimum scaling dimension. It is indeed possible to generalize the solution of ABA for “non-minimum string modes”. However, no systematic attempt has been made. Further discussion will be provided in Sec. 5.

I – Type-(a) Odderons:

As pointed out earlier, the $j = 1$ mode survives in the supergravity limit, and it can be identified with the protected CFT operator of the type $Tr(F_{\perp}F_{\perp}Z^k) + \cdots$. This conformal primary, just as the case for the Pomeron, can formally be considered as a descendent of super-conformal primary in the $sl(2)$ sector. However, there can be many spectral curves emanating from this protected configuration at $j = 1$, for $\lambda$ finite. We assume that the all-coupling formula (3.10) for the slope function applies to the set $\Delta_{O,a}$, corresponding to the “minimum twist” set, and we shall proceed to calculate the Odderon intercept to higher orders in $1/\sqrt{\lambda}$ under this assumption. The validity of this assumption will be examined in the next section.

That is, we assume that, for type-(a) Odderons, $\beta_n(\tau_a) = \beta_n(4 + k)$, with $\beta_n$ given by the same functions used for the case of Pomeron. With this we can find the intercept for any $k$, but for simplicity,

---

[3]: See [40][41] for a discussion and comparison to ABJM theory.
and to study the case most relevant for QCD, we write the result in the limit $k \to 0$. Hence $\tau(a) = 4$, and we take advantage of the expansion $\binom{3.20}{\tau}$. Under the assumptions made above, $c_i$ can be found by solving the equation

$$0 = 4^2 + \beta_1(\lambda, 4)(j_0 - 1) + \beta_2(\lambda, 4)(j_0 - 1)^2 + \beta_3(\lambda, 4)(j_0 - 1)^3 + \beta_4(\lambda, 4)(j_0 - 1)^4 + \cdots ,$$

iteratively. It is possible to directly adopt the calculation previously done for the Pomeron intercept in Sec. 3, with $c_n$ given by $\binom{3.20}{\tau}$, by evaluating equation $\binom{3.25}{\tau}$ at $\tau = 4$, after shifting the spin $j$ by 1. One finds

$$\alpha_{O,a} = 1 - \frac{8}{\lambda^{1/2}} - \frac{4}{\lambda^{3/2}} + \frac{13}{\lambda^2} + \frac{96\zeta(3) + 41}{\lambda^{5/2}} + \frac{288\zeta(3) + 1249}{\lambda^{3}} + \frac{-720\zeta(5) + 192\zeta(3) + 159}{\lambda^{5}} + \cdots . \quad (4.12)$$

This intercept $\alpha_{O,a}$ is illustrated in Fig. 3. Note that coefficients $\{c_n\}$ change signs, with $c_1, c_2 < 0$, $c_3, c_4, c_5 > 0$, and $c_6 < 0$. We also note that, in the range $0 < 1/\sqrt{\lambda} < 0.3$, where strong coupling is expected to be useful, the intercept $\alpha_{O,a}$ is below $j = 1$. As one increases $1/\sqrt{\lambda}$ beyond 0.2, interestingly, it begins to turn around and move towards $j = 1$, as it should, only after $c_4$ and higher terms are kept. Note as well that the intercept does not continue to blow up, but begins to flatten out as higher orders are taken into account, e.g., with $c_6 < 0$. This behavior fits nicely with the expected matching behavior to first order weak coupling calculation, at $1/\sqrt{\lambda} \approx 0.3$, as shown in Fig. 4.

Notice that it is a simple exercise to determine the coefficients in an expansion of the type $\binom{3.5}{\tau}$ for the Odderon spin function $j(\nu, \tau)$.

II – Type-(b) Odderons and $\tau_b = k \to 0$: As stated earlier, although there are no obvious structural differences between type-(a) and type-(b) Odderon spectral curves in the diffusion limit, one crucial difference is the absence of a protected local...
CFT operator at $j = 1$ at $\tau_b \to 0$, in the supergravity limit. For $k \neq 0$, the simplest set of local operators one can identify are $Tr[(D^+)^{-1} F_{\pm\pm} Z^k]$. These operators decouple however in the $k \to 0$ limit. It is likely that the lowest physical mode on the $k = 0$ spectral curve occurs at $j = 3$ is $Tr[F_{\pm\pm} F_{\pm\pm} F_{\pm\pm}]$ and it is not protected. It has been suggested\footnote{B. Basso, private communication.} that, for $j = 3, 5, \cdots$, these type-(b) modes could be associated with local operators: $Tr[D^+ F_{\pm\pm} F_{\pm\pm} F_{\pm\pm}] + \cdots$. However, these lead to a different system of $sl(2)$ spin chain, and a separate analysis is required\cite{19, 61, 62, 63}. An equally interesting possibility is to consider the sequence $Tr[(F_{\pm\pm} F_{\pm\pm})^{(j-1)/2} F_{\pm\pm}]$. Neither sequence leads to well-defined local operators at $j = 1$. For this and other considerations, we do not expect the all-coupling formula (3.10) to work for type-(b) Odderon, specially for the $k = 0$ mode. Therefore, we shall proceed to carry a more general analysis \textit{without} assuming the Basso formula for the slope function, $\alpha_1$. We shall search for, if any, universal behavior which might survive in the limit of $\tau_b \to 0$.

We proceed by making the expansion for $\beta_n$, (4.10), as before, and arrive at

$$
(\Delta O_b(j, \tau_b) - 2)^2 = \tau_b^2 + 2 \lambda^{1/2} \left( 1 - \frac{b_{1,1}}{\lambda^{1/2}} + \frac{b_{1,2}}{\lambda^{3/2}} + \frac{b_{1,3}}{\lambda^{2}} + \cdots \right) (j - 1) + 2 \left( b_{2,0} + \frac{b_{2,1}}{\lambda} + \frac{b_{2,2}}{\lambda^{3/2}} + \cdots \right) (j - 1)^2 + 2 \lambda^{-1/2} \left( b_{3,0} + \frac{b_{3,1}}{\lambda^{1/2}} + \frac{b_{3,2}}{\lambda} + \frac{b_{3,3}}{\lambda^{3/2}} + \cdots \right) (j - 1)^3 + O((j - 1)^4).
$$

(4.13)

Note, with the exception of $\tau_b = k$ and $b_{1,0} = 1$, other coefficients $b_{n,j}$ are \textit{unspecified}. Expanding $\alpha_O$ as in (4.11), after substituting into (4.13), the coefficients $c_i$ can be determined iteratively, e.g., leading to formulas essentially given by Eq. (3.20). To be more explicit, we can directly express all coefficients $c_i$ in terms of $b_{n,i}$. For the first few terms we have, from (3.20),

$$
c_1(\tau_b) = -\frac{\tau_b^2}{2},
$$

$$
c_2(\tau_b) = \frac{\tau_b^2}{2} b_{1,1},
$$

$$
c_3(\tau_b) = \frac{\tau_b^2}{2} \left( -b_{1,1}^2 + b_{1,2} - b_{2,0} \tau_b^2 \right),
$$

$$
c_4(\tau_b) = \frac{\tau_b^2}{2} \left( b_{1,1}^3 - 2b_{1,1}b_{1,2} + b_{1,3} + (3b_{1,1}b_{2,1} - b_{2,1}) \frac{\tau_b^2}{2} \right),
$$

$$
c_5(\tau) = \frac{\tau_b^2}{2} \left( -b_{1,1}^4 + \cdots + (b_{1,1}^2 b_{2,0} + \cdots) \frac{\tau_b^2}{2} + (b_{2,0} + \cdots) \frac{\tau_b^4}{2} \right),
$$

$$
c_6(\tau_b) = \frac{\tau_b^2}{2} \left( b_{1,1}^5 + \cdots + (10b_{1,1}^2 b_{2,0} + \cdots) \frac{\tau_b^2}{2} + (10b_{1,1} b_{2,0} + \cdots) \frac{\tau_b^4}{2} \right).
$$

(4.14)

From \cite{19}, we expect that $b_{n,j}$ to be polynomials of $\tau_b^2$. Note that in the limit $\tau_b \to 0$, all coefficients vanish as $\tau_b^2$, e.g., $c_1 \sim \tau_b^4$, $c_2 \sim \tau_b^6$, etc., for arbitrary values for coefficients $b_{n,i}$. It is also easy to verify that, $c_{n+1}/c_n \sim O(1)$, for $\tau_b \to 0$. We thus arrive at an important result where, $c_n = O(\tau_b^2) \to 0$, for all
\( \tau_b \to 0 \). It follows that the leading Odderon intercept for the set-(b), for \( \tau_b = 0 \), remains at
\[
\alpha_{O,b} = 1,
\] (4.15)
without higher order correction in an \( 1/\sqrt{\lambda} \) expansion. This is the long promised result. To state it more graphically, in the limit \( \tau_b \to 0 \), higher order corrections can change the shape of the spectral curve, without changing its minimum at \( \Delta = 2 \).

For \( \tau_b \neq 0 \), more information is required in order to determine the higher order expansion for their intercepts, e.g., adopting the all-coupling formula (3.10). We will not engage in this exercise here, but note that due to the generality of the above derivation, the \( \tau_b = 0 \) result would survive for all possible expansions of \( \beta_n \).

5 Conclusions

We have focussed in this study on the leading \( C = \pm 1 \) Regge singularities, the Pomeron and Odderon respectively, in strong coupling. Central to our discussion is the notion of spectral curve \( \Delta(j) \) for single-trace gauge invariance operators of \( \mathcal{N} = 4 \) SYM. Identifying \( \Delta(j) \) in weak coupling remains involved due to possible operator mixings [60]. In strong coupling, spectral curves for leading twist can be identified with bulk degrees of freedom for \( D = 10 \) SUGRA on \( AdS_5 \times S^5 \) [59]. The Pomeron trajectory can be associated with the Reggeized Graviton, while the Odderon trajectories correspond to Reggeized anti-symmetric \( AdS_5 \) Kalb-Ramond tensor-fields. With string-vertex operators [5, 20], the relevant single-trace CFT operators and their associated string modes for both Pomeron and Odderon sectors can be identified.

We began by first providing a general discussion on Regge limit in CFT from the perspective of light-cone OPE, and showed how the double-Mellin transforms (2.4) and (2.11) can be used directly in a Minkowski setting. A Regge dictionary (2.13) is established between CFT in coordinate representation and that based on AdS/CFT in a momentum treatment. An important and probably difficult theoretical problem left unresolved is to determine the conditions required in a conformal theory to allow for this representation in the double-Mellin plane. Is this conformal Regge representation a generic property of all 4D Lorentz invariant conformal theories, or is it restricted to a smaller class of theories?

Due to integrability, these spectral curves can in principle be determined [34], with their inverse \( j(\Delta) \) being symmetric under \( \Delta \leftrightarrow 4 - \Delta \), due to conformal invariance. In this study, we have focussed on “short strings” where each spectral curve takes on a relatively simple form in the large \( \lambda \) limit while maintaining the \( \Delta \leftrightarrow 4 - \Delta \) symmetry. In particular, by adopting the approach advocated in [40, 41, 40–41], higher order expansion in \( 1/\sqrt{\lambda} \) for the Pomeron intercept has been carried out recently [16–19]. We have generalized this analysis for the Pomeron sector to include non-zero R charge, [3, 20], and have also extended the treatment to the case of Odderons, [12, 13, 12–13]. For the case of the Pomeron with large classical R charge, it would be interesting to see the appearance of this trajectory in the Regge limit of four-point functions of heavy operators computed in [63] at strong coupling.
Since our result depends crucially on the small spin expansion (3.9), it is worth adding a brief comment on the slope function \( \alpha_1(\lambda, \tau) \), as promised earlier. The set of gauge invariant operators, designated symbolically by \( \text{Tr}(D^S Z^\tau) + \cdots \), for \( \tau > 2 \), spans a subspace on which the dilation operator closes in the large \( N \) limit, leading to a set of spectral curves \( \Delta_{Z,k}(S, \tau) \), labelled by an index \( k \). Each curve has a distinct slope, \( \alpha_{1,k}(\lambda, \tau) \), at \( S = 0 \). Our focus here is for strong coupling, where, in the diffusion limit, \( \Delta_Z \approx \tau + (\sqrt{\lambda}/\tau)S \). Therefore, all these curves are degenerate in this limit. These slope functions can be found via ABA, without "wrapping corrections", where the index \( k \) can be specified by a set of filling fractions \([15, 40, 41]\). The "minimum filling", (or "minimum mode" configuration), leads to the original Basso formula. Clearly, there are many additional solutions. In our current treatment, the minimum filling solution has been used for both the Pomeron and the type-(a) Odderon sectors. Note that for both the Pomeron and the type-(a) Odderon keeping the \( O(1/\sqrt{\lambda}) \) result for the intercept stemming from the Basso formula agrees with the Pomeron and Odderon intercepts found independently by perturbing about the supergravity limit \([5, 20]\).

Let us turn next to the type-(b) Odderon. As we have stated earlier, in the super-gravity limit, the \( k = 0 \) mode decouples at \( j = 1 \), and, for \( \lambda \) finite, its physical modes begin at \( j = 3, 5, \cdots \). In Sec. 4.1 we have carried out a more generally analysis without invoking the all-coupling formula (3.10). Our treatment is based on the structure of large \( \lambda \) expansion. Given the diffusion result of \( \alpha_{O,b} = 1 \), for \( k = 0 \), Eq. (4.15) follows to all orders. The phenomenon of decoupling also has its counter part in flat space string theory. For \( d = 4 \), Kalb-Ramond tensor field does not lead to a spin-1 massless particle since \( B_{\mu\nu} \) has only one independent transverse component. As a 4-d Regge trajectory, its higher string recurrences at \( j = 3, 5, \cdots \) are physical. Therefore, the issue of decoupling can be accomplished by an appropriate vanishing of the coupling, while the dynamics of the whole trajectory remains. (Instead, at \( t = 0 \), \( B_{\mu\nu} \) leads to a spin-0 state, the “axion”.) A more detailed analysis will be presented elsewhere.

In this study, we have not fully explored the consequence of super-symmetry, in particular the possibility of more general symmetry patterns for spectral curves \( \Delta_Z(S, \tau) \). A useful study is a careful examination for the spectral curves for other modes of SUGRA, e.g., scalars, vectors, etc. A preliminary finding involves the possibility of having a more complex structure, e.g., the symmetry about \( \Delta = 2 \) is realized by a pairing of spectral curves, with one symmetric about \( \Delta = 0 \) and the other about \( \Delta = 4 \). Equally interesting is the question for the Odderon intercept in strong coupling from a brane construct alone, without imposing super-symmetry, and its relation to results obtained in weak coupling.

We have focussed in this study on the leading planar limit. Note that, in the planar limit, the conformal amplitude growth with a power of \( s \), or, equivalently, \( 1/\sqrt{u} \), which would violate the flat-space Froissart bound. Clearly, in order to address the issue of Froissart bound for CFT’s, one must consider the extension to higher orders in \( 1/N^2 \). One such re-summation is given by the eikonal approximation. From the perspective of light-cone OPE, one must begin including multiple-trace primaries in order to carry out such analysis. It is also interesting to examine the effect of confinement deformation. Since scale invariance is broken in the IR, adopting Poincare-patch for \( AdS \) is most suitable for such a treatment. Instead of spectral curves \( \Delta(j) \), one now has ordinary Regge singularities \( \alpha(t) \) at positive \( t \), leading to discrete physical states at integral \( j \), e.g., glueballs. One also finds that our double-Mellin representation, (2.4) and (2.11), reduces to a single Mellin (Regge) representation, with a sum over Regge trajectories.
These and other related issues will be addressed in future publications.
