ABSTRACT

We conduct a detailed investigation of the properties of the stellar initial mass function (IMF) in two massive early-type lens galaxies with velocity dispersions of $\sigma \approx 245$ km s$^{-1}$ and $\sigma \approx 325$ km s$^{-1}$, for which both HST imaging and X-Shooter spectra are available. We compare the inferences obtained from two fully independent methods: (i) a combined gravitational lensing and stellar dynamics (L&D) analysis of the data sets employing self-consistent axisymmetric models, and (ii) a spectroscopic simple stellar population (SSP) analysis of optical line-strength indices, assuming single power-law IMFs. The results from the two approaches are found to be in agreement within the 1-$\sigma$ uncertainties. Both galaxies are consistent with having a Salpeter IMF (power-law slope of $x = 2.35$), which is strongly favoured over a Chabrier IMF ($x = 1.8$), with probabilities inferred from the joint analysis of 89% and 99%, respectively. Bottom-heavy IMFs significantly steeper than Salpeter ($x > 3.0$) are ruled out with decisive evidence (Bayes factor $B > 1000$) for both galaxies, as they exceed the total mass derived from the L&D constraints. Our analysis allows, for the first time, the inference of the low-mass cut-off of the IMF ($M_{\text{low}}$). Combining the joint L&D and SSP analyses of both galaxies, we infer an IMF slope of $x = 2.22 \pm 0.14$, consistent with Salpeter IMF; and a low-mass limit $M_{\text{low}} = 0.13 \pm 0.03 M_\odot$, just above the hydrogen burning limit.

Key words: gravitational lensing: strong — galaxies: elliptical and lenticular, cD — galaxies: kinematics and dynamics — galaxies: stellar content — galaxies: structure

1 INTRODUCTION

The stellar initial mass function is a fundamental quantity to understand the evolution and structure of galaxies, since it is crucial in determining many key properties of stellar populations and galaxies, such as star formation rates and galaxy stellar masses. While it has long been assumed that the IMF is universal, given that the IMF appears to be largely invariant throughout the Local Group (Kroupa 2001; Chabrier 2003; Bastian et al. 2010; Kroupa et al. 2013), in recent years numerous extra-galactic studies have provided mounting evidence that the steepness of the IMF profile might vary with galaxy mass, stellar velocity dispersion or morphological type (e.g. Trager et al. 2000; Graves et al. 2009; Treu et al. 2010; van Dokkum & Conroy 2010; Auger et al. 2010; Barnabè et al. 2012, hereafter B12; Geha et al. 2013; Dutton et al. 2013). In particular, there are strong indications that massive elliptical galaxies are characterized by a classic single power-law Salpeter (1955) IMF (dN/dm $\propto m^{-x}$ with slope $x = 2.35$, where $N$ is the number of stars of mass $m$), possibly becoming steeper with increasing total galaxy mass (see e.g. Grillo et al. 2009; van Dokkum & Conroy 2010; Barnabè et al. 2009, 2011; Cappellari et al. 2012; Spiniello et al. 2011, 2012; van Dokkum & Conroy 2012; Conroy & van Dokkum 2012; Sonnenfeld et al. 2012; Ferreras et al. 2013; Tortora et al. 2013)

Understanding the trend in the IMF slope is necessary to determine how the dark matter content of galaxies changes with mass, and thus to provide important insight into galaxy evolution mechanisms. Several works (e.g. Padmanabhan et al. 2004; Tortora et al. 2009; Graves & Faber 2010; Barnabè et al. 2011) have shown that, under the assumption of a universal IMF, the inferred dark matter fraction within the inner regions of early-type galaxies (ETGs) increases with the total mass. However, it remains unclear whether (and how much) this effect can be countered by the observed vari-
ation in the IMF slope, and consequently to what extent (if at all) the actual dark matter content and of ETGs scales with total mass.

The combination of gravitational lensing with stellar (or gas) dynamics has been proven to be a very robust and powerful method to investigate the mass structure of both early- and late-type galaxies beyond the local Universe (e.g. Treu & Koopmans 2004; Jiang & Kochanek 2007; Czoske et al. 2008; Koopmans et al. 2009; Barnabè et al. 2013). When lensing and kinematic data of sufficient quality are available, this technique can also make it possible to put firm constraints on the stellar mass of the analyzed galaxy (see van de Ven et al. 2010; Dutton et al. 2011; B12), which can then be compared to the results of SSP modeling to draw inferences for the shape of the IMF of the galaxy. In this Letter we follow an analogous approach: by taking advantage of high-quality X-Shooter spectroscopic observations, we perform a fully self-consistent joint L&D analysis of two massive lens ETGs: SDSS J0936+0913 ($\sigma = 243 \pm 11$ km s$^{-1}$ at $z = 0.164$) and SDSS J0912+0029 ($\sigma = 326 \pm 12$ km s$^{-1}$ at $z = 0.190$), hereafter J0936 and J0912, respectively. The inferences for the stellar masses are then compared against the corresponding results from a completely independent method, viz., a spectroscopic SSP study of the analyzed galaxy (see van de Ven et al. 2010; Dutton et al. 2011; B12), which can then be compared to the results of SSP modeling to draw inferences for the shape of the IMF of the galaxy.

2 DATA SET

Both galaxies were originally observed with HST as part of the Sloan Lens ACS Survey (SLACS). We refer to Bolton et al. (2008) and Auger et al. (2009) for a detailed presentation of all the SLACS spectrophotometric data sets. For the analysis presented here, we make use of the high-resolution F814W images of the lens systems. An elliptical B-spline model of the surface brightness distribution of the deflector is used to produce the galaxy-subtracted image that is used for the lensing modelling (see Bolton et al. 2008).

For both systems, UVB–VIS X-Shooter spectra with signal-to-noise high enough to perform SSP analysis (S/N > 50) were obtained as part of the X-Shooter Lens Survey (XLENS, Spinello et al. 2011). X-Shooter observations of J0912 and J0936 were carried out during two runs between 2011 and 2013 in slit mode (UVB: R = 3300 with 1′.6 × 11′. slit; VIS: R = 5400, with 1′.5 × 11′. slit). The total exposure time on target was ~ 2500 sec for J0912 and ~ 5000 sec for J0936, with a typical seeing for both observations of ~ 0′.65. The data were reduced using the ESO X-Shooter pipeline v1.5.7. Stellar kinematic parameters were measured with the Penalized Pixel Fitting code of Cappellari & Emsellem (2004).

3 SIMPLE STELLAR POPULATION MODELLING

For our analysis we use the SSP models of CvD12. To constrain the IMF slope, age and [α/Fe] of the stellar populations, we follow the approach described by Spinello et al. (2013). We use the nearly IMF-independent indicators Hβ, Mg b, Fe5270, and Fe5335 to constrain age and [α/Fe], while the combination of CaH1 and four TiO features are used to measure the low-mass end of the IMF. We compare the indices of each galaxy with grids of SSPs spanning a range of log($\mu_{\alpha}$/age/Gyr) = [0.8, 1.15] and [α/Fe] = [−0.2, +0.4] dex for different values of the IMF slope ($x = 1.8 \pm 3.5$), which is assumed to be a single power-law. In CvD12 the abundance variations of single elements are implemented at fixed [Fe/H], which implies that the total metallicity $Z$ varies from model to model. For each model we calculate the χ² and obtain a probability distribution function (PDF) via the likelihood function and assuming uniform priors over the above described ranges. We then marginalize over age and [α/Fe] to obtain the best-fitting slope of the IMF and its uncertainty for each system: $x_{J0936} = 2.10 \pm 0.15$ and $x_{J0912} = 2.60 \pm 0.30$.

To determine $\chi^2_\alpha$, we use the isochrones at solar [Fe/H] from the state-of-the-art stellar evolution code DSEP (Dartmouth Stellar Evolution Program, Chaboyer et al. 2001), selecting IMF slope, age, and [α/Fe] inferred from the line-strength analysis (see Table I). Each $\chi^2_\alpha$ includes the contribution from stellar remnants and gas ejected from stars at the end of their life-cycles. The lowest mass limit in the DSEP isochrones is $M_{\text{low}} = 0.115 M_\odot$. We extrapolate the luminosities for lower mass down to the hydrogen burning limit of $M_{\text{low}} = 0.08 M_\odot$ (e.g. Kumar 1963; Grossman 1970), using a spline. We note that stars below ~ 0.115 $M_\odot$ remain mostly invisible in current spectral lines for any reasonable IMF slope (CvD12) and therefore we can move $M_{\text{low}}$ without any real impact on the spectra and on the line-strength measurements. Finally, we use the luminosities derived in Auger et al. (2009) to translate these numbers into stellar masses. The results are presented in Table I.

4 GRAVITATIONAL LENSING AND STELLAR KINEMATICS MODELLING

We carry out an in-depth analysis of the mass and dynamical structure of the two lens systems by employing the fully Bayesian CAULDRON code (detailed by Barnabè & Koopmans 2007 and B12), which is designed to conduct a self-consistent combined modelling of both the lensing and kinematic constraints.

We adopt a flexible two-component axially-symmetric mass model for the lens galaxy. For the dark matter component, motivated by the findings of cosmological simulations, we use a generalized Navarro-Frenk-White (gNFW) halo characterized by four free parameters, namely the inner density slope $\gamma$, the axial ratio $q_0$, the halo concentration parameter $c_2$, and the virial velocity $v_{\text{vir}}$ (i.e. the circular velocity at the virial radius). The density profile of the luminous mass component is obtained by deprojecting the multi-Gaussian expansion (MGE) fit to the observed surface brightness distribution of the galaxy, that has become the de facto standard in state-of-the-art dynamical studies of galaxies (e.g., the ATLAS$^{3D}$ project. Cappellari et al. 2011). The free parameter $\chi^2_\alpha$, or equivalently the total stellar mass $M_\star \equiv \chi^2_\alpha L_{\text{tot}}$, sets the normalization of the luminous distribution.

This mass profile is then used to simultaneously model both the lensing data set, by employing a pixelated source reconstruction method, and the stellar kinematic observables, where the quantity $v_{\text{rot}}(R) = \sqrt{v^2_{\text{rot}}(R) + \sigma^2(R)}$, where $v_{\text{rot}}$ and $\sigma$ denote the line-of-sight projected stellar rotation velocity and velocity dispersion, respectively. The construction of the dynamical model is based on the flexible Jeans anisotropic MGE technique (JAM, see Cappellari 2008), which allows for orbital anisotropy, specified by the meridional plane anisotropy parameter $b = \sigma^2_p / \sigma^2_\parallel = 1/(1 - \beta_i)$.
and log within the uncertainties with the findings from the most accurate and matter fractions within one effective radius measurement of the IMF slope for the two systems, inferring tightly constrained: we find log of the two analyzed systems. The posterior PDFs for the quantity presented in Table 2, together with the one-dimensional marginalized posterior PDFs derived from the combined L&D analysis. As discussed by B12, we choose very broad uninformative priors encompassing the entire range of realistic parameter values and allowing for a wide variety of galaxy models. In particular, the prior on the velocity dispersion-halo virial mass relationship as determined by, e.g., Bundy, Treu, & Ellis (2007) for massive ellipticals, allowing for a broad standard deviation.

| parameter | prior | posterior J0936 | prior J0912 | posterior J0912 |
|-----------|-------|-----------------|------------|----------------|
| \( v_{\text{vir}}/\text{km s}^{-1} \) | \( N(350, 150) \) | \( 124^{+160}_{-88} \) | \( N(475, 200) \) | \( 470^{+160}_{-130} \) |
| \( \gamma \) | \( U(0, 2) \) | \( 0.92^{+0.72}_{-0.64} \) | \( U(0, 2) \) | \( 0.46^{+0.41}_{-0.30} \) |
| \( c_{-2} \) | \( U(0, 50) \) | \( 6.3^{+18.4}_{-6.1} \) | \( U(0, 50) \) | \( 7.2^{+13.8}_{-2.7} \) |
| \( q_b \) | \( LN(1, 0.3) \) | \( 0.93^{+0.25}_{-0.18} \) | \( LN(1, 0.3) \) | \( 0.54^{+0.10}_{-0.08} \) |
| \( M_\star/10^{11}M_\odot \) | \( U(0, 10) \) | \( 3.1^{+0.18}_{-0.30} \) | \( U(0, 35) \) | \( 10.28^{+0.52}_{-0.62} \) |
| \( b \) | \( U(0, 5) \) | \( 0.89^{+0.37}_{-0.31} \) | \( U(0, 5) \) | \( 1.94^{+0.24}_{-0.21} \) |

In the prior columns, \( U(a, b) \) denotes a uniform distribution over the open interval \((a, b)\), \( N(\mu, \sigma) \) and \( LN(a, b) \) denote a normal and lognormal distribution, respectively, with \( a \) being the central value for the variable and \( b \) the standard deviation (for the log of the variable, in the case of \( LN \)). In the posterior columns, we list, for each parameter, the median value of the corresponding marginalized posterior PDF and the uncertainty quantified by taking the 68% credible interval (i.e., the 16th and 84th percentiles). See Sect. I for a description of the six free model parameters.

The adopted prior distributions for the six free parameters are presented in Table 1 together with the one-dimensional marginalized posterior PDFs derived from the combined L&D analysis. As discussed by B12, we choose very broad uninformative priors encompassing the entire range of realistic parameter values and allowing for a wide variety of galaxy models. In particular, the prior on \( v_{\text{vir}} \) is based on the velocity dispersion-halo virial mass relationship as determined by, e.g., Bundy, Treu, & Ellis (2007) for massive ellipticals, allowing for a broad standard deviation.

5 RESULTS AND DISCUSSION

In this Letter we focus on the inferences for the total stellar mass of the two analyzed systems. The posterior PDFs for the quantity \( \log M_\star/M_\odot \) are shown in Fig. 1 as histograms. The values are tightly constrained: we find \( \log M_\star/M_\odot = 11.52^{+0.02}_{-0.04} \) for J0936 and \( \log M_\star/M_\odot = 12.01^{+0.03}_{-0.01} \) for J0912. The corresponding dark matter fractions within one effective radius \( R_e \) are \( f_{\text{DM}} = 0.06^{+0.10}_{-0.01} \) and \( f_{\text{DM}} = 0.19^{+0.08}_{-0.03} \), respectively. These values are in agreement within the uncertainties with the findings from the most accurate dynamical studies of local ellipticals, which measure median \( f_{\text{DM}} \approx 0.10 \pm 0.25 \) (see Williams et al. 2009, Thomas et al. 2011, Cappellari et al. 2013). We note that J0936 is at the lower limit of these values and is marginally consistent with having no dark matter contribution within its inner regions.

From the SSP analysis described in Sect. I we obtain a direct measurement of the IMF slope for the two systems, inferring \( x_{\text{J0936}} = 2.10 \pm 0.15 \) and \( x_{\text{J0912}} = 2.60 \pm 0.30 \). From these values we derive the total \( M_\star \) of the two objects and we compare them with the corresponding \( M_\star \) independently determined from the lensing and dynamics study, as illustrated in Figure 1. As clearly seen, the stellar masses inferred from the two methods are consistent within the one-sigma uncertainties for both galaxies.

The first result is that both galaxies are consistent with a Salpeter-like IMF: for J0912, \( x = 2.35 \) is within the 1-sigma uncertainties derived from the SSP analysis, and is actually preferred over the maximum a posteriori (MAP) slope \( x_{\text{J0912}} = 2.6 \) with an 84% probability (Bayes factor \( B = 5.2 \)). For J0936, a Salpeter IMF is slightly disfavoured with respect to the MAP slope \( x_{\text{J0936}} = 2.1 \), albeit only marginally (\( B = 0.40 \)). In general, even though we see a weak steepening of the best-fit IMF when going from the slightly sub-Salpeter J0912 (\( x \approx 2.2 \)) to J0912 (best-fit slope \( x \approx 2.4 \)), there is no compelling indication of an IMF slope trend with galaxy mass from this data set.

A Chabrier IMF, on the other hand, is ruled out for both systems with a high degree of confidence. A Salpeter-like IMF is preferred over a Chabrier-like one at 89% probability \( (B = 8) \) for J0936, and at 99% probability \( (B = 96) \) for J0912, corresponding in the second case to very strong evidence. This confirms the findings of several studies of ETGs, using a variety of methods (e.g., Grillo et al. 2009, Spiniello et al. 2011, Cappellari et al. 2013).

We note that the SSP results are obtained under the assumption of a single power-law IMF. A broken power-law (as proposed by Kroupa 2001) or a log-normal IMF (as in Chabrier 2003), both described by two different slopes for different mass ranges ("tailed IMFs"), will be considered in future works. In particular, we plan to apply the method presented here for the analysis of the entire XLENS sample (Spiniello et al., in prep.) testing different assumptions for the IMF with the value of \( M_\text{low} \) as well as the peak mass characterizing a tapered IMF as free parameters.

Some works based on absorption-line strengths (e.g., Ferreras et al. 2013) have suggested that the most massive ETGs \((\sigma \gtrsim 200\text{ km s}^{-1})\) might have increasingly bottom-heavy IMFs, with slopes significantly steeper than Salpeter, i.e. \( x = 3.0 \pm 3.5 \). Even though one might have concluded from the inferences drawn from the spectroscopic SSP analysis alone that the massive galaxy J0912 is consistent with an \( x = 3.0 \) super-Salpeter IMF, that scenario is clearly ruled out when also the results of the combined L&D analysis are brought into the picture. In fact, for J0912 (and even more so for J0936) a Salpeter IMF is favoured over a steep IMF by a Bayes factor \( B > 1000 \), corresponding to decisive evidence. More intuitively, adopting a super-Salpeter IMF results in a stellar mass exceeding the galaxy total mass predicted by the combined model, and therefore this scenario must be ruled out as unphysical.

Finally, the approach presented in this Letter allows for the first time a resolution of the long-standing problem of constraining the low-mass cut-off for the IMF. In previous studies, \( M_\text{low} \) has been treated as a fully unconstrained parameter, despite being critical to

1 Very similar values of the Bayes factors are obtained if we compare the Chabrier IMF with the MAP slopes rather than with Salpeter.

2 It has been argued that \( B > 1000 \) is high enough to be used as conclusive forensic evidence in criminal trials, cf. Kass & Raftery 1995, and references therein.
Figure 1. Comparison of the total stellar masses $M_\star$ inferred from the combined lensing and dynamics analysis (histogram) with the $M_\star$ determined from the spectroscopic SSP modelling of line-strength indices, for different values of the IMF slope (indicated above the tics on the horizontal bars). The solid red curve and the grey band denote, respectively, $M_\star$ for the MAP slope and the best-fit probability density function (Salpeter) and 50% for $M_\star$ as determined from the combined L&D analysis. The analysis conducted so far have very little effect on the spectra and on the line-index measurements. Luckily, this degeneracy can be broken when adding the information of the IMF slope, as suggested by, e.g., CvD12. The dashed blue curve gives the inference for $M_\star$ when we adopt the value $M_{\text{low}} = 0.115 M_\odot$ assumed by CvD12. The dash-dotted green curve gives the inference for $M_\star$ when using the MAP slope and the best-fit $M_{\text{low}}$ value.

determine $\Upsilon_\star$. Stars with masses below $\sim 0.15 M_\odot$ have very little effect on the spectral lines in the optical and near-infrared for any assumed IMF slope (CvD12) but they give a non-negligible contribution to the total mass budget of the system (Worthey 1994). Therefore, it is impossible to determine $M_{\text{low}}$ from spectroscopic studies alone, since varying this parameter does not have any real impact on the spectra and on the line-index measurements. Luckily, this degeneracy can be broken when adding the information of the IMF slope, as suggested by, e.g., CvD12. The inferred total stellar mass increases significantly for the steeper IMF slopes, i.e. around 25% for $x = 2.35$ (Salpeter) and 50% for $x = 3.0$. For J0936, the constraints on $M_\star$ are not good enough to discriminate between the two possibilities; on the other hand, in the case of J0912 (considering the MAP slope $x_{\text{J0912}} = 2.6$), there is decisive evidence in favour of $M_{\text{low}}^D$ with $B = 401$, corresponding to 99.8% probability.

We combine the results of the L&D and SSP analyses of both galaxies to derive the joint inferences on the IMF slope and cut-off. To this purpose, we use the DSEP isochrones extrapolated down to $0.06 M_\odot$ to compute the V-band $\Upsilon_\star$ for different values of the IMF slope and $M_{\text{low}}$ for both ETGs; these $\Upsilon_\star$ are used to convert the observed luminosities into stellar masses. The probability density for this stellar mass is then determined from the posterior PDF of the IMF slope and cut-off. The solid red curve shows $M_\star$ when using the MAP slope and the best-fit $M_{\text{low}}$ value. The dash-dotted green curve gives the inference for $M_\star$ when using the MAP slope and the best-fit $M_{\text{low}}$ value.
samples drawn by varying $x$, $M_{\text{low}}$, and ETG luminosity, to sample the joint lensing, dynamics and SSP posterior. Finally we combine the posteriors derived from the two galaxies, and marginalize over luminosity to obtain the joint 2-D posterior PDF, which is shown in Fig. 2. The resulting marginalized MAP values are $x = 2.22 \pm 0.14$ for the IMF slope, and a low-mass cut-off $M_{\text{low}} = 0.13 \pm 0.03 M_\odot$.

6 CONCLUSIONS

In this work, for the first time, we compare the results of a state-of-the-art combined lensing and dynamics analysis of two early-type galaxies with the corresponding inferences from a spectroscopic SSP study of line-strength indices. This is made possible by the exquisite quality of the data sets available for the two systems, J0936 and J0912, including HST high-resolution imaging and high signal-to-noise X-Shooter spectra.

We model simultaneously the lensing and kinematic data sets by adopting a flexible, axisymmetric, two-component mass distribution for the dark halo and the luminous profile (both self-gravitating), and solving the Jeans anisotropic equations. We derive tight constraints on the total stellar mass and dark matter fractions (within one $R_e$) of the two galaxies, i.e. $\log_{10} M_{\star}/M_\odot = 11.52^{+0.02}_{-0.03}$ and $f_{\text{DM}} = 0.06^{+0.10}_{-0.03}$ for J0936 and $\log_{10} M_{\star}/M_\odot = 12.01^{+0.03}_{-0.03}$ and $f_{\text{DM}} = 0.18^{+0.08}_{-0.08}$ for J0912, independent of the IMF. These dark matter contents are in agreement, within the uncertainties, with the findings of dynamical studies of local ellipticals (e.g. Cappellari et al. 2013). By comparing the posterior PDFs for $M_\star$ derived from this combined analysis with the completely independent results from the spectroscopic SSP study of the two systems, under the assumption of a single power-law IMF, we draw the following conclusions on the properties of their IMFs:

(i) The modelling of the line-strength indices (adopting solar metallicity and a cut-off mass $M_{\text{low}} = 0.115 M_\odot$) provides a direct determination of the IMF slopes for the two lenses, namely $x_{\text{J0936}} = 2.10 \pm 0.15$ and $x_{\text{J0912}} = 2.60 \pm 0.30$. The total stellar masses inferred from this method are completely consistent within the one-sigma uncertainties with the results obtained from the combined lensing and dynamics analysis, which is a fully independent approach that makes no assumptions on the IMF.

(ii) For both galaxies, an IMF with slope close to Salpeter ($x = 2.35$) provides a much better description than a Chabrier profile: statistical analysis based on the calculation of evidence ratios (i.e., Bayes factor), shows that a Salpeter IMF model is preferred over a Chabrier one with 89% and 99% probability for J0936 and J0912, respectively.

(iii) Bottom-heavy IMFs significantly steeper than Salpeter, i.e. with slopes $x > 3.0$, are ruled out by decisive evidence (Bayes factor $B > 1000$) for both galaxies. The values for $M_\star$ implied by these super-Salpeter IMFs unphysically exceed the total galaxy mass derived from the combined lensing and dynamics analysis. This result contradicts the findings from absorption line spectroscopy studies (see e.g. Ferreras et al. 2013) which support IMF slopes $x = 3.0$ - 3.5 for massive ETGs such as those considered here ($c_{\text{J0936}} = 243 \pm 11 \text{ km s}^{-1}$ and $c_{\text{J0912}} = 326 \pm 12 \text{ km s}^{-1}$).

(iv) For the system J0912, a low-mass IMF cut-off of $M_{\text{low}} = 0.08 M_\odot$ (corresponding to the hydrogen burning limit) is ruled out with a probability of 99.8% in favor of the value $M_{\text{low}} = 0.115 M_\odot$ assumed by DSEP. For J0936, instead, it is not possible to reliably discriminate between the two values.

(v) By combining the L&D and SSP inferences of the two lenses, we obtain the marginalized MAP values $x = 2.22 \pm 0.14$ for the IMF slope and $M_{\text{low}} = 0.13 \pm 0.03 M_\odot$, consistent with a Salpeter-like IMF and a low-mass cut-off slightly higher than the hydrogen burning limit.
