Abstract

Background: The sciatic nerve is a peripheral nerve and is more vulnerable to compression with subsequent short- or long-term neuronal dysfunction. The current study was designed to elucidate the possible ameliorative effect of L-carnitine and sildenafil (SIL) on sciatic nerve crush injury. We sought to determine the effects of L-carnitine, a neuroprotective and a neuro-modulatory agent, and sildenafil citrate, a selective peripheral phosphodiesterases inhibitor on modulating neuro-degenerative changes due to sciatic nerve compression.

Materials and methods: The comparative effect of L-carnitine (at an oral dose of 20 mg/kg/day) or SIL citrate (20 mg/kg/day orally) administration for 21 days was studied in a rat model of sciatic nerve compression. Sciatic nerve sections were subjected to biochemical, histological, ultrastructure, and immunohistochemical studies to observe the effects of these treatments on neurofilament protein.
Results: The sciatic nerve crush injury group (group II) showed a significant decrease in tissue catalase (CAT), superoxide dismutase (SOD) and increase in malondihyde (MDA) as compared to control group (P < 0.01). Histological changes in the form of degenerated and vacuolated axoplasm with areas of nerve fiber loss and pyknotic nuclei were reported. The blood vessels were dilated, congested with areas of hemorrhage and mononuclear cell infiltration. Histomorphometrically, a statistically significant reduction in the nerve fibers number, mean axon cross-sectional area, myelin sheath thickness and a significant increase in collagen fibers percentage (P < 0.05) as compared to control group. Immunohistochemically, neurofilament protein was significantly downregulated as proved by a significant reduction in mean area % of neurofilament expression. L-carnitine ameliorated the studied parameters through its neuroprotective effect while Sildenafil (SIL) is a selective peripheral phosphodiesterases (PDE-5) inhibitor had improved crush injury parameters but with less extent than L-carnitine.

Conclusions: These findings indicate the valuable effects of L-carnitine administration compared to that of SIL citrate in alleviating the serious debilitating effects of sciatic nerve crush injury. Our results provide a new insight into the scope of neuroprotective and, neuro-regenerative effects of L-carnitine in a sciatic nerve compression model.

Key words: sciatic nerve, compression, L-carnitine, sildenafil citrate, histopathology, oxidative stress, immunohistochemistry

INTRODUCTION

It is vital for the characteristic morphology of the peripheral nerve bundle to remain intact for normal autonomic, motor, and sensory nerve functions. Peripheral nerves injury results in transient or long-term neuronal dysfunction, often lead to subsequent social and economic disability [37].

The various types of nerve injuries include compression (crush), stretch, and laceration [10]. Acute traumatic peripheral nerve injury induces tissue lesions at the damaged site, such
as axonal degeneration, demyelination, multifocal loss of nerve fibers, oedema in the endoneurium as well as enhanced vascular permeability with axoplasmic flow block [8,55]. Persistent nerve crushing can affect microcirculation which play main role in nerve regeneration, oxygen supply and maintain neural conduction [23]. Release of nerve compression (reperfusion) lead to release of nerve tissue pressure and subsequent redeposition of nutrients and oxygen in high pressure and enhance free radicals formation leading to lipid peroxidation and tissue damage [71].

The chances of sensory function returning are still very poor even with expert surgical repair, and this may have subsequent adverse effects on motor function, particularly fine motor skills [34]. If medical treatment is not available, death can occur in the injured nerve cell, resulting in functional loss [47]. Various agents have been tested via experimental trials in an attempt to prevent this loss of motor function [13,20].

Carnitine is an amine with vitamin- like characteristics and a non-amino acid structure [6]. There are two forms of carnitine; L-carnitine and it’s analogues. These have a protective effect against tissue ischaemia and subsequent reperfusion damage [55]. It is responsible for the transportation of fatty acids from the cytoplasm to the mitochondria, allowing ATP production via oxidative phosphorylation process [36]. It may also play a role in acetylcholine synthesis and release. Acetyl L-carnitine also plays a role in neuron repair and balances NGF expression in the central nervous system [63].

Researches have evaluated the neuroprotective effect of acetyl-L-carnitine in patients suffering from neuropathic pain, nerve function loss, and damaged sciatic nerve. Furthermore, marked improvement and symptom relief has been reported in these patients [14, 32,55].

Pettegrew et al. [51] studied the neuromodulatory and neuroprotective effects of carnitine on Alzheimer’s disease, revealing its beneficial effects on cognitive function and neurodegeneration in these patients. L-carnitine has also been shown to possess analgesic [22] and antidepressant properties [11]. Moreover, L-carnitine has been reported to play a key role in treating diabetes-induced retinopathy and neuropathy as shown by a decrease in the level of
L-carnitine in the sciatic nerve. Additionally, it exerts antinflammatory activity by decreasing IL-6, IL-1β, and TNF-α levels [69] and antifibrotic activity [46].

Sildenafil (SIL) is a selective peripheral phosphodiesterases (PDE-5) inhibitor and has been shown to have a therapeutic effect in improving erectile dysfunction by increasing the level of intracellular cGMP [25,50]. Moreover, SIL also has a beneficial effect on several diseases [64] such as having peripheral antinociceptive properties, resulting in the accumulation of intracellular cGMP [30]. Additionally, it exacerbates the antinociceptive character of different analgesics such as morphine, celecoxib, and indomethacin via the nitric oxide-cyclic guanosine monophosphate (NO-cGMP) pathway [17,44]. According to the American Heart Association [5], SIL increases the level of brain neurotransmitters that enhances stroke recovery. Furthermore, it can improve the neurological effects of brain neurotransmitters when administered to rats within 2–24 hours of stroke.

The present study was designed to elucidate the possible ameliorative effect of L-Carnitine and SIL on sciatic nerve crush injury. To observe these effects, we conducted histological, ultrastructure, morphometric, and quantitative immunohistochemical studies in rats administered these agents.

MATERIALS AND METHODS

Animals

In this study, sixty-five adult female albino rats were obtained from the Menofyia University animal house located in the Faculty of Medicine. Each rat weighed approximately (200 –220 gm). The rats were housed in metal cages under suitable laboratory conditions (12 hr light/dark cycle, with lights on from 07:00–19:00). The environment was maintained a temperature of 22±2 °C during the experimental period. The rats had access to tap water and standard food ad libitum. The study was conducted in accordance with all international guidelines for animal care. All experimental protocols and animal care were approved by the Experimental Animal Ethics Committee, Menoufia University, Shibin Elkom, Egypt. This
The experiment was prepared and designed according to guidelines approved by the Menofia University Ethical Committee.

**Experimental design**

The female rats were divided into four groups.

**Group I:** was designated as the control group, and was subdivided into 4 groups (n = 5 rats/group):

- **subgroup IA,** in which rats did not receive any experimental treatment through the study duration
- **subgroup IB (sham operation subgroup),** in which the sciatic nerves were exposed on the right hindlimb of each rat without crushing.
- **subgroup IC (L-carnitine subgroup),** in which rats were orally administered with L-Carnitine (100 mg/kg/day) which was dissolved in distilled water for 21 days [6].
- **Subgroup ID (SIL citrate subgroup),** in this group rats were orally administered SIL citrate (20 mg/kg/day) which was dissolved in normal saline for 21 days [39].

**Group II animals (sciatic nerve crush injury group):** were subjected to sciatic nerve crush injury (n = 15).

**Group III animals (L-carnitine-treated sciatic nerve crush injury group)** were orally administered with L-carnitine at the same dosage and schedule as subgroup IC, and were subjected to sciatic nerve crush injury (n = 15).

**Group IV animals (SIL citrate-treated sciatic nerve crush injury group)** were administered with SIL citrate at the same dosage and schedule as subgroup ID, and were subjected to sciatic nerve crush injury (n = 15).
The experimental duration was 21 days. Twenty-four hours after the final dosages were administered; rats were anesthetized with an overdose of phenobarbital via inhalation (200 mg/kg) then sacrifice by rapid cervical dislocation. The proximal segments of the sciatic nerve of the right hindlimb were obtained from each animal using scissors.

Drugs and chemicals

**L-carnitine.** L-carnitine base (350 mg) was obtained in tablet from MEPACO–MEDIFOOD (Arab Company of Pharmaceuticals and Medicinal Plants, Sharkeya, Egypt). Each tablet was dissolved in distilled water to obtain the required dose, and was used immediately subsequent to dilution.

**SIL citrate.** SIL citrate (VIAGRA) was obtained in tablet form, and each tablet contained 50 mg of the active ingredient (Pharmaco-Vigilance Center, Pfizer Pharmaceutical Company, Dokki, Egypt). The estimated dose was suspended in normal saline.

Surgical procedure

Rats were anesthetized before surgery via intraperitoneal injection of ketamine (100 mg/kg body weight) (Pfizer, New York, USA) and 10 mg/kg xylazine (Xyla-Ject, ADWIA Pharmaceuticals Co, El Obour City, Egypt) [53,74].

Nerve crushing was performed on the right hind limb. The area of incision was shaved, and skin was sterilized with 10% povidone iodine. A 2-cm incision was then performed along the proximal half of the line between the greater trochanter and the knee joint. To expose the sciatic nerve, a splitting incision was made in the gluteal muscle. The vastus lateralis and biceps femoris muscle were then separated using artery forceps [53].

Nerve crush was performed by applying sustained pressure for 15 seconds to the exposed sciatic nerve with artery forceps, at an area 1 cm proximal to the sciatic nerve division into the tibial and common peroneal nerves. To confirm complete nerve crush injury
with intact epineurium, a microprobe was used to elevate the nerve slightly and confirm the appearance of a clear area within the nerve as shown (Fig. 1). Finally, the skin incision was sutured, and rats were kept warm by placing them on a heating pad [53]. Each rat received (10 mg/kg) kataflam (Novartis Pharmaceuticals Corporation, East Hanover, New Jersey, USA) via intramuscular injection for pain relief and (10 mg/kg) flumox (Egyptian Int Pharmaceutical industries CO EIPICo, 10th Ramadan City, Egypt) via intramuscular injection to prevent secondary bacterial infection. The local antibiotic Biovitracin spray (Egyptian Company for Advanced Pharmaceuticals, Giza, Egypt) was also applied once daily in spray form (two puffs) to treat local infection. All medications were used for 5 days to facilitate healing. The right hind limb was obtained after animal scarifications and divided into two samples. The first was subjected to histological study and the second was kept in an eppendorf tube and sored at – 80 °C until the day of the experiment for biochemical study.

**Evaluation methods**

**Biochemical study.** The frozen sciatic nerve specimens were homogenized in cold 0.9% Nacl using glass homogenizer. The homogenates were centrifuged to obtain the supernatant fraction for CAT, SOD and MDA determination [70]. Sciatic nerve tissue MDA (malondialdehyde) level were estimated using Mihara and Uchiyama [43] method depend on estimating color absorbance of complex result from MDA and thiobarbituric acid mixing in an acidic environment at 532 nm using turnable microplate reader (Molecular Devices, LLC, Sunnyvale, CA, USA). MDA values were expressed as nmol/gm wet sciatic tissue.

Catalase level in sciatic nerve tissue (CAT) were measured using Goth [26] method which depend on measuring the absorbance of yellow colored complex developed from ammonium molybdate and hydrogen peroxide at 405 nm. Tissue CAT result was expresses as U/mg protein. Tissue superoxide dismutase (SOD) was evaluated using Sun et al [60] method. It depends on nitroblue tetrazolium reduction by O₂⁻ and measuring the absorbance of the resulting purple formazan molecule at 560 nm using turnable microplate reader (VERSA
The final SOD activity was obtained by dividing SOD activity on total protein level and expressed as U/mg protein.

**Histology.** Sciatic nerve specimens were fixed in 10% formal saline for 24 h and then processed for paraffinization. The paraffin blocks were cut into slices (of 5 μm thickness), and hematoxylin & eosin (H&E) staining was conducted to determine the general architecture of the sciatic nerve [59].

**Histochemistry.** Paraffin slices were stained with Masson trichrome (MT) stain to visualize collagen fibers [9].

**Immunohistochemistry.** The avidin–biotin peroxidase method was used for immunohistochemical study of neurofilament protein expression. Paraffin-embedded tissue sections were placed on to poly-L-lysine coated glass slides, followed by deparaffinization and rehydration in ethyl alcohol. To block endogenous peroxidase activity, the slides were incubated with 3% hydrogen peroxide in a humidity chamber for 10–15 min, then washed three times with PBS for 10 min. Sciatic nerve sections were incubated with primary antibody (polyclonal rabbit anti-neurofilament-200, N4142, Sigma-Aldrich) for 1 hour at 4 °C. Primary antibody was diluted at 1:80 in PBS and kept in a humidity chamber. Sections were incubated with secondary antibody (1:200, ab97055; Abcam, Cambridge, MA, USA) in PBS for 30 min at 37 °C after washing three times with PBS. Sections were incubated with the avidin–biotin–peroxidase complex (Universal Elite ABC kit PK-6200; Vectastain, Burlingame, CA, USA) for 30 min followed by rinsing with PBS. Sections were then stained with Vexation diaminobenzidine (DAB) (Kit HK153–5K; Biogenex, San Ramon, CA, USA) for 10 min to visualize the areas of antibody immunostaining. Finally, the sections were washed with tap water. The sections were counterstained with hematoxylin, dehydrated, cleared, and covered with glass mounted with Canada balsam (C1795, Sigma-Aldrich). The primary antibody was replaced by PBS and served as a negative control. Rat cerebral cortex was used as a positive control. Positive expression of neurofilament protein in the cytoplasm of the nerve fibers was indicated by a brown color.
**Transmission electron microscopy.** Sciatic nerve was cut into small pieces (1 mm³) and kept in 2.5% gluteraldehyde for 24 h for fixation. Using an ultra-microtome, (0.5–1µm slices) were obtained as semithin sections and subjected to toluidine blue staining for analysis via light microscopy. The blocks were trimmed, and some areas were selected for ultrathin sections preparations. The blocks were encapsulated in a copper grid. Uranyl acetate and lead citrate stains were used for ultrathin sections staining, followed by examination using a transmission electron microscope (Seo-Russia) in the Alexandria Medical Research Institute [9].

**Quantitative assessment**

Image J software (version K.1.45) was used for measuring the following parameters:

1- The number of myelinated axons (nerve fiber number);
2- Axon cross-sectional area;
3- Myelin sheath thickness in apparently non-degenerated nerve fibers;
4- The percentage of collagen fibers;
5- Mean percentage of the area of positive neurofilament protein expression.

The quantitative measurements were performed by using a Leica DML B2/11888111 microscope contained Leica DFC450 camera and were evaluated and measured. For each of the chosen groups, five slides were selected from each specimen. Ten non-overlapping fields were picked up for measurement at a 40× magnification.

**Statistical analysis**

Image analysis data were obtained, and their mean ± standard deviation (SD) were calculated and statistically analyzed. The different groups were compared using various parameters using both one-way analysis of variance (ANOVA) then post-hoc Bonferroni test to determine statistical significance. Data were considered statistically significant and highly
significant at \( P < 0.05 \) and 0.001, respectively. The results were listed in tables and plotted graphically.

**RESULTS**

**Bistochemical results**

Oxidative enzymes results in all studied groups are represented in Figure (2.A&B). Compared with control group (Group I), tissue CAT and SOD activities were significantly decreased (79.31±46 vs 154.18±50 U/mg protein) and (86.82±26.31 vs 191.4±45 U/mg protein) respectively while MDA was significantly increased (6.61±2.51 vs 1.53±1.1 nmol/mg prt) in (Group II) crush group (\( p <0.05 \)) as compared to control group. After L-carnitin treatment, tissue CAT and SOD activities were significantly elevated (139.25±45 vs 79.31±46) and (175.32±41 vs 86.82±26.31 U/mg protein) respectively and MDA level declined significantly (2.06±0.98 vs 6.61±2.51 nmol/mg prt) as compared to (Group II) (\( p <0.05 \)). However, administering SIL also increased CAT and SOD activities (99.54±39 vs 79.31±46) and (109.62±27 vs 86.82±26.31 U/mg protein respectively) and decreased MDA activity (4.95±1.92 vs 6.61±2.51 nmol/mg prt) as compared to group II but still difference is not statistically significant.

**Histological results**

H&E-stained longitudinal sections of the different studied groups were examined using light microscopy. In the control group (group I), the nerve fibers were parallel, and were packed together with Schwann cell nuclei between the nerve fibers (Fig. 3A). Sections from the sciatic nerve crush injury group (group II) showed various histological changes, including degenerated and vacuolated axoplasm with areas of nerve fiber loss with pyknotic nuclei. The other sections showed dilated and congested blood vessels with areas of hemorrhage and mononuclear cell infiltration (Fig. 3B,C).
Additionally, in the sections from the L-Carnitine-treated sciatic nerve crush injury group (group III), regeneration and some vacuolation was observed in most nerve fibers, with Schwann cell nuclei observed between them (Fig. 3D). Moreover, in the SIL citrate-treated sciatic nerve crush injury group (group IV), most nerve fibers showed widespread vacuolation (Fig. 3E).

The longitudinal sciatic nerve sections from group I control rats showed minimal collagen fibers between nerve axons after MT staining (Fig. 3F). A marked increase in collagen fibers was observed in sections from group II compared to the group I control sections (Figs. 3G). A mild increase in collagen fibers was observed in group III (Fig. 3H), while a moderate increase in collagen was observed in group IV (Fig. 3I). A statistically significant increase in the percentage of collagen fibers (P < 0.05) was observed in both groups II and IV (18.33 ± 2.51 and 13.0 ± 1.65, respectively) compared with that in group I (1.67 ± 0.58). However, the percentage of collagen fibers significantly decreased in group III when compared with that in group IV (5.50 ± 0.71 versus 13.0 ± 1.65, P < 0.05). Furthermore, the percentage of collagen fibers in group III was reduced compared with that in group II (5.50 ± 0.71 versus 18.33 ± 2.51, P < 0.05) (Fig. 3J).

**Immunohistochemical results**

Immunohistochemical staining of the longitudinal sciatic nerve sections revealed that, neurofilament protein was significantly downregulated in groups II and IV (3.80 ± 0.52 and 7.40 ± 0.89, respectively) compared with its expression in group I (34.40 ± 3.1) (P < 0.05). Moreover, neurofilament protein was significantly downregulated in group IV compared with in group II (P < 0.05). In contrast, neurofilament protein was significantly upregulated in group III compared with its expression in group II (28.60 ± 2.64 versus 3.80 ± 0.52, P < 0.05) (Fig. 4A–D).

**Results of toluidine blue staining of semithin sections**
Control group semithin sections stained with toluidine blue demonstrated that, part of the nerve bundles were surrounded by perineurium. The myelinated nerve fibers had regular oval or rounded myelin sheaths, and were stained dark blue around the light blue-stained axons. The blood vessels could also be observed (Fig. 5A). Group II showed degenerative changes in the myelin coat, with disintegrated myelin fragments completely covering normal fiber sections areas or compressing the axons. Few nerve fibers with thin myelin could be seen (Fig. 5B). Group III showed restoration of the normal appearance of myelin sheaths compared with the control group (Fig. 5C). Group IV had many myelinated nerve fibers with an irregular myelin sheath, with myelin in-folding and out-folding and degenerated axons (Fig. 5D).

There was a statistically significant reduction in the number of nerve fibers (P < 0.05) in both groups II and IV (2.00 ± 0.11 and 4.41 ± 0.89, respectively) when compared with that in the control group (28.24 ± 4.44). However, the number of nerve fibers increased in group III compared with that in group II (24.29 ± 1.89 versus 2.00 ± 0.11, P < 0.05). Moreover, the number of nerve fibers increased in group III when compared with that in group IV (24.29 ± 1.89 versus 4.41 ± 0.89, P < 0.05)(Fig. 5E).

There was a statistically significant decrease in the mean axon cross-sectional area in groups II and IV (8.68 ± 1.75 vs 14.11 ± 2.89 μm², respectively) compared with that in the control group (40.95 ± 2.87 μm², P < 0.05). However, a significant reduction was observed in the mean axon cross-sectional area in group IV compared with that in group III (14.11 ± 2.89 vs 36.26 ± 2.53 μm², P < 0.05). Moreover, there was a significant increase in the mean axon cross-sectional area in group III compared with that in group II (36.26 ± 2.53 vs 8.68 ± 1.75 μm², P < 0.05)(Fig. 5E).

The thickness of the myelin sheath significantly decreased (P < 0.05) in groups II and IV (0.84 ± 0.14 , 0.91 ± 0.06 μm vs 1.55 ± 0.39 respectively) as compared with the control group. Moreover, a highly significant increase (P < 0.05) in myelin sheath thickness was reported in group III compared with that in group IV (1.84 ± 0.4 vs 0.91 ± 0.06 μm, respectively). Additionally, there was a highly significant reduction (P < 0.05) in myelin
sheath thickness in group II compared with that in group III (0.84 ± 0.14 vs 1.48 ± 0.40 μm, respectively) (Fig. 5F).

**Transmission electron microscopy analysis**

TEM analysis of the control group showed myelinated axons surrounded by a thick regular myelin sheath. The axoplasm contained mitochondria, neurofilaments, and microtubules. Axons were enclosed by Schwann cell cytoplasm, and the Schwann cell had large a nucleus with peripheral heterochromatin. Groups of unmyelinated nerve fibers were also be observed (Fig. 6A).

TEM examination of group II showed irregular and distorted myelin sheaths. The sheaths did not have a uniform thickness, and some had multiple vacuolations. Other myelin sheaths showed separation in the myelin sheath lamellae. Retracted degenerated myelinated axons with small vacuolation were observed in the axoplasm (Fig. 6 B–E). The Schwann cell nucleus was irregular and indented with peripheral chromatin condensation. In another section, the Schwann cell cytoplasm had multiple vacuolations and dense bodies (Fig. 6 E,B).

Group III mostly demonstrated normal myelinated nerves with a regular compact myelin sheath and homogenous axoplasm. However, some nerve fibers still had splitting in the myelin sheath (Fig. 8F). Group IV had some nerve fibers with irregular myelin sheaths, with focal thickening compressing the axons (Fig. 6 G)

**DISCUSSION**

Peripheral nervous system injuries are increasing in frequency, and serve as a medical hazard. Such injuries mostly affect young adults, resulting from traffic accidents, falls, and surgery [42]. These injuries may lead to lifelong debilitating disability, potentially resulting in loss of organ functions [76]. Feng and Yuan [21] concluded that, drugs can be a reliable
method for obtaining acceptable functional recovery in crush injury, but that surgical repair is a more precise option for transection injury.

In a peripheral nerve crush injury, the mechanism of injury is unclear, as some nerve integrity is maintained. Emel et al. [19] have demonstrated that the possible mechanism of crush injury is due to mechanical compression, followed by edema and ischemia of the crushed nerve fibers. Moreover, enhanced arachidonic acid metabolism and both intracellular and extracellular endoperoxide accumulations occur at the lesion site as sequelae of morphological changes and deficient oxygen supply [73]. Zhang and Chopp [74] concluded that, neurorepair processes (angiogenesis and neurogenesis) are activated in adults after the occurrence of various pathological conditions.

Sciatic nerve crush injury result in vasa nervosa damage and impairment of nerve blood flow if persistent compressive ischemia last for long period [45]. The pathology of crush injury in sciatic nerve may be due various factors such as endogenous chemical mediators accumulation, apoptosis, free radical generation and ischaemia [59]. Oxidative stress gives rise to cellular damage with activating apoptosis. Free oxygen radicles (ROS) are the main source of lipid peroxidation (LPO) and induce oxidative stress by modulating antioxidant activities [52]. Various antioxidant enzymes as CAT, SOD and glutathione peroxidase (GSH) can be involved in detoxification of ROS. CAT and SOD capable of scavenger peroxide and superoxide anions [12]. Therefore, their elevated level in tissue pointed to raised antioxidant activity [58]. Hence, during cell injury reduction in antioxidant enzymes activity such as SOD, CAT and glutathione peroxidase [62]. On the other hand, MDA and myeloperoxidase activity was reported to increase due to inflammatory reaction associated with tissue injury leading to direct membrane function impairment and indirect cellular component damage [71].

In the current study tissue CAT and SOD activities were significantly decreased in crushed group as compared to control group (p<0.05). While MDA was significantly increased (p<0.05). Our findings were in line with Kocaoglu et al. [38] how reported same findings. They explained that, nerve compression induce blood brain barrier disruption and
nerve edema with decrease peripheral nerve oxygen supply and morphological changes. The previous findings enhance arachidonic acid metabolism and permit unstable endoperoxides accumulation both extracellular and intracellular. Moreover, reperfusion after nerve compression causes free radical formation similar to ischemia-perfusion injury [73]. Nervous system injuries stimulate glutamate production, glutamate receptor activation and calcium ion accumulation with subsequent induction of ROS, hydrogen peroxide, and superoxide anion formation. Lipid peroxidation cascades are initiated by oxidative stress leading to cell membrane damage during the initial period after injury [18].

Light microscopic examination of the H&E sections from the specimen of nerve crush injury group showed degenerated and vacuolated axoplasm, with areas of nerve fiber loss and pyknotic nuclei. Other sections, showed dilated and congested blood vessels with areas of hemorrhage and mononuclear cell infiltration. These findings were in accordance with those obtained by [4,40,61]. These findings were supported by a significant reduction in the number of sciatic nerve fibers (P < 0.05) in the sciatic nerve crush group compared to that in control group. This was reflected by the weak anti-neurofilament antibody expression observed in the crush group. Tomassoni et al. [63] reported the apparent loss of both myelinated and unmyelinated nerve fibers after nerve ligation. Moreover, Di Cesare Mannelli et al. [15] determined that, more significant axonal degeneration and nerve trunk apoptosis, along with Schwann cells DNA fragmentation in the nuclei, were reported in the distal end of the nerve.

In the current study, MT staining revealed a significant increase in the perineurial and endoneurial collagen fibers in group II compared to those in group III and the control group (P < 0.05). This can be attributed to fibrin deposition as a consequence of sciatic nerve injury, resulting in enhanced nerve damage, alteration of the composition of the extracellular matrix and the suppression of Schwann cell migration [16]. However, an inflammatory reaction with proinflammatory cytokines occurs due to fibrin deposition and macrophage accumulation. This which may induce tissue injury, but its main role lies in mechanisms involved in tissue regeneration [49]. Moreover, other studies involving sciatic nerve crush injury have observed an increased number of endoneurial fibroblasts and an accumulation of connective tissue in the interfiber endoneurium [35].
In this manuscript, we observed misexpression and weak neurofilament expression in group II, there was strong neurofilament expression in the nerve fibers in group III. Additionally, the mean percentage of the area of neurofilament expression increased in a significant manner (P < 0.05) in the control group compared to groups II and VI. Our results were in accordance with those obtained by Song et al. [58] who observed that, a decrease in positive neurofilament expression in the nervous system microtubules was correlated with diabetes and various nerve injuries. This results from a disturbance in the synthesis and transport of neuronal substances, and therefore, the irregular activity in the nervous system.

The immunohistochemical findings from our study were supported by a significant increase in the number of sciatic nerve fibers (P < 0.05) in group III compared to that in group II. These immunohistochemical findings were in line with those obtained by Khabiri et al.[33] who reported that, olfactory ensheathing cells transplantation accelerates nerve axon myelination and regeneration following crush nerve injury. Omura et al. [48] concluded that, neurofilament expression in sciatic nerve axons was correlated with early signs of nerve regeneration.

In the present study, TEM examination of the nerve crushed group showed irregular and, distorted myelin sheaths with lamellar separation and degenerated myelinated axons. However, the Schwann cell nucleus was irregular and indented with peripheral chromatin condensation, while multiple vacuolations and dense bodies were reported in its cytoplasm. These results are consistent with previous research demonstrating myelin sheath degeneration and splitting [1,2]. Furthermore, Tamaddonfard et al. [61] suggested that, Schwann cells accumulation and the attraction of macrophages to the nerve injury site can assist scavengers of degenerated nerve axons and myelin sheath fragmentation to enhance the initiation of nerve regeneration. Moreover, previous studies have suggested that, the regeneration process is influenced by inflammatory changes and oxidative stress at the injury site and the distal nerve [28].

Yuan and Feng [72] demonstrated that, Wallerian degeneration can occur after sciatic nerve crush injury, which involves nerve axon degeneration, Schwann cell accumulation,
myelin sheath disintegration and macrophage infiltration. Moreover, Schwann cells and macrophages play a major role in the secretion of various cytokines and a variety of inflammatory mediators, such as interleukin (IL) 1-β, tumor necrosis factor (TNF)-α and interferon, all of which regulate Wallerian degeneration [35]. Additionally, damaged tissue proximal to the injured area may inhibit axonal extension and impair the healing process. Wallerian degeneration may assist macrophages and white blood cells accumulation to remove the damaged myelin sheath and injured axons. Furthermore, accelerated Schwann cell division and differentiations plays a major role in axon renewal [41,66].

L-carnitine is a potent antioxidant with neuroprotective potential and can suppress oxidative damage in neurogenerative diseases such as Parkinson’s and Alzheimer’s disease [3,27]. It is considered as an exogenous neurotrophic factor, decreasing neuronal loss after nerve injury and improving neuronal regeneration [67]. Collectively, we explored the possible ameliorative effects of L-carnitine administration on sciatic nerve crush damage. L-carnitine administration improved the antioxidant status as proved in group III. Administration of L-carnitine after crush nerve injury improved all biochemical parameters as tissue CAT and SOD activities were significantly elevated and MDA level declined significantly (p<0.05) as compared to (Group II). It also reduce the damage to the axon and myelin sheath, with a near-normal structure observed in the nerve fibers. Our results were in accordance with findings reported by Avsar et al. [6] who studied the alleviating effect of L-carnitine on sciatic nerve crush injury in rats. It was found that, L-carnitine has an effect on the recovery of sciatic nerve function as well as enhancing nerve regeneration and suppressing injury-induced degeneration in the nerve axon and it’s myelin sheath. Wilson et al. [68] and Babicova et al. [7] explained that, L-carnitine blocks the cell death pathway at the mitochondrial level by limiting reactive oxygen species synthesis in addition to reducing the nitric oxide (NO) and nitric oxide synthase (NOS) levels.

SIL is a PDE-5 inhibitor with neuroprotective effect, which is initiated by stimulating neurotrophic factors encountered in neuronal regeneration and survival [29]. In this manuscript, SIL administration in group IV led to a mild improvement in the histopathological findings and biochemical parameters as proved by increased CAT and SOD activities and
decreased MDA activity as compared to group II but still difference is not statistically significant. These results were in line with those obtained by Vakharia, et al. [65] who studied the neuroprotective properties of SIL on facial nerve functional recovery following nerve crush injury. The study concluded that, SIL administration following facial nerve crush injury had only a mild transient effect on the functional recovery of the facial nerve, despite its neuroprotective effect in previous studies. On the other hand, Garcia et al. [24] found that SIL can ameliorate oxidative and inflammatory stress on pelvic ganglion neurons after inducing damage to bilateral cavernosal nerve through compensatory elevated antioxidant enzymes. These findings were proved by increase NADPH complex expression such as p22-phox and toxol which represent the main source of ROS formation. It indicates higher ability for superoxide production. It may also induce anti-inflammatory feedback. This was thought to occur by regulating inflammatory cytokine expression by preventing leukocyte accumulation and migration near the neuronal lesion. Moreover, Jeong et al. [31] studied the effect of SIL on the kidneys of streptozotocin-diabetic rats and reported diminished oxidative stress and reduced pro-inflammatory cytokine expression.

Quantitative morphometric study demonstrated a significant increase in in the thickness of the myelin sheath, the number of nerve fibers, and the axon cross-sectional area with L-Carnitine treated group was observed. These findings were in agreement with those obtained by Avsar et al. [6] who concluded that L-Carnitine had an excellent ability to prevent nerve function loss following nerve injury, accelerate nerve degeneration, and ameliorate axon and myelin sheath degeneration. On contrary to insignificant increase in the previous parameters in group treated with SIL.

According to the histopathologic, immunohistochemical, and histo-morphometric findings, L-Carnitine had an alleviating effect on nerve crush injury lesions, and this effect was greater than that observed by SIL administration. This is suggestive of the more potent antioxidant and anti-inflammatory effect of L-Carnitine with respect to nerve injuries.

CONCLUSIONS
Nerve crush injury can result in serious debilitating effects which can be partially relieved by administering substances such as nutrients and drugs. In this study, by means of histopathology, electron microscopy, and morphometric studies, it was demonstrated that, these effects may be alleviated by L-carnitine administration and minimally ameliorated by SIL uptake. It provide a new scope to the neuroregenerative effect of L-carnitine on nerve compression.

**Ethical approval**

All relevant institutional, national, and international guidelines related to animal use and care was followed. All methods and strategies were managed according to the guidelines approved by the Animal Research Ethics committee, Menoufia University, Faculty of Medicine.

Figure 3. Representative photomicrographs of longitudinal rat sciatic nerve sections from each of the experimental groups. (A) Control group I showing myelinated nerve fibers (F), with Schwann cell nuclei (arrow) between the fibers. (B) Group II showing discontinuity of most nerve fibers (red arrow), with vacuolated axoplasm (V), some pyknotic nuclei (arrow head), and areas of nerve fiber loss (*). (C) Group II showing nerve fibers with widespread vacuolations (V), mononuclear cell infiltration (curved arrow), and dilated congested blood vessels (BV) with areas of hemorrhage (notched arrow). (D) Group III showing regeneration of most of the nerve fibers (F). Some vacuolation (V) can be seen in the fibers with Schwann cell nuclei (arrow). (E) Group IV
showing widespread vacuolations (V) (hematoxylin and eosin staining, scale bar 20 µm, 40× magnification). (F) Control group I showing minimal collagen fibers between the nerve axon. A marked increase in collagen fibers was observed in group II (G), a mild increase was observed in group III (H) and a moderate increase was observed in group IV (I) (Masson’s trichrome staining, scale bar=20 µm, 40× magnification). (J) Histogram demonstrating a significant increase in the percentage of collagen fibers in both groups II and IV when compared with that in control group I (0,+P < 0.05). The percentage of collagen fibers was significantly reduced in group III compared with that in group II (*P < 0.05), and significantly decreased in group III compared to group IV (*P < 0.05).

Figure 4. Representative neurofilament immunostaining in rat sciatic nerve sections from the different experimental groups. Immunostaining revealed that neurofilament was significantly downregulated in groups II and IV compared with the adult control group I (0,+P < 0.05) (A,B,D), and also in group IV compared with group II (+P < 0.05) (B,D). In contrast, a significant upregulation was observed in group III compared with that in group II (*P < 0.05) (B, C) (scale bar 20 µm, 40× magnification).
Figure 5. Representative photomicrographs of the stained semithin rat sciatic nerve sections from the different experimental groups. (A) Control group I showing bundles of nerve fibers. The myelinated nerve fibers have regular myelin sheaths (M) stained dark blue around the axons (A). The perineurium surrounds the nerve bundles (P), and blood vessels (BV) can be seen. (B) Degenerative changes of the myelin coat in group II, with disintegrated myelin fragments covering the sections with normal fibers (arrow) or compressing the axons (A). Some have thickened myelin (M) and some nerve fibers have thin myelin (arrowhead). (C) Group III showing restoration of the normal appearance of myelin sheaths (M) and axons (A) in most myelinated nerve fibers. (D) Group IV showing many myelinated nerve fibers with irregular myelin sheaths (M), with in-folding, out-folding, and degenerated axons (A) (Toluidin blue, Scale bar 10 µm, 1000× magnification). (E) Histogram for the number of nerve fibers and the mean axon cross-sectional area showing a significant reduction in the number of nerve fibers and the mean axon cross-sectional area in both groups II and IV compared to that in group I (0, +P < 0.05). There were also increased numbers of nerve fibers in group III compared to in groups II and IV (*P < 0.05). (F) Histogram showing a significant a significant reduction in the mean of myelin sheath thickness in group II and IV compared to that in group I (0P < 0.05). A significant increase in myelin sheath thickness was reported in group III compared to that in group II and IV (*P < 0.05). However, a significant reduction in in the mean of myelin sheath thickness was observed in group IV compared to that in group III (+P < 0.05).
Figure 6. Representative electron micrographs of rat sciatic nerve sections from the different experimental groups (A) Cross-section of control group showing myelinated axons (A) ensheathed with a myelin sheath (M) of uniform thickness. The electron-dense dots present in the axons are neurotubules, neurofilaments (arrow), and mitochondria (arrow head). Schwann cells (Shc) have large nuclei (N) and enclose the myelinated nerve fibers. Unmyelinated nerve fibers are indicated (UM). (B) Cross-section of the group II showing an irregular myelin sheath (M) with multiple vacuolations (V). These are enclosed by Schwann cells (Shc), which have vacuolated (V) cytoplasm and dense bodies (DB). We observed a compressed axon (A) with a small vacuolation (arrow head). (C) Cross-section of the group II showing separation in the myelin sheath lamellae (yellow arrow). (D) Cross-section of the group II with a thin and irregular myelin sheath (M) and axon retraction (*). (E) Longitudinal section of group II showing distortion of the myelin sheath (arrow) and an irregular indented Schwann cell nucleus (ShcN) with peripheral chromatin condensation. (F) Cross-section from group III, showing that myelinated nerves appear nearly normal with a regular compact myelin sheath (M) and homogenous axoplasm (A). Some of the myelin sheaths have either splitting (yellow head arrow) or in-folding (red arrow), while others are thin and irregular (chevron arrow). (G) Cross-section from group IV, showing an irregular myelin sheath (arrow) with focal thickening in some nerve fibers (red arrow) compressing the axons (A). (A–E, 17500× magnification) (F,G, 5000× magnification).
