I. INTRODUCTION

The thermodynamics of strongly interacting matter at non-vanishing isospin chemical potential, $\mu_I$, is relevant in different realms of physics, since there are several systems where the amounts of protons and neutrons are not the same. In the formation process of neutron stars, the initial proton fraction in supernovae is $\sim 0.4$, which reduces with time to values of less than 0.1 in cold neutron stars [1, 2]. In the early universe, shortly after the Big Bang, a large asymmetry in the lepton sector that could shift the equilibrium conditions at the cosmological quark-hadron transition is allowed [3]. And, of course, in high-energy heavy-ion collisions, the proton to neutron ratio is $\sim 2/3$ in Au or Pb beams.

The phase diagram of QCD at finite temperature and isospin density is rich in phenomenology and has been investigated for over a decade [4, 5]. Since then, several studies were performed within effective models, on the lattice and most recently even perturbatively [6–25]. Although Monte Carlo simulations do not suffer from the sign problem since the fermion determinant remains real at nonzero $\mu_I$, lattice calculations at non-zero isospin have been performed so far with unphysical quark masses [7, 8, 10, 11, 13, 14, 24], which still limits their quantitative predictive power.

In this paper, we use next-to-leading-order in perturbation theory to investigate the effects of a finite isospin density on the thermodynamics of cold ($T = 0$) strongly interacting matter which includes nonzero quark masses. Whenever possible, our results are compared to lattice data from Ref. [26]. The paper is organized as follows: in Section II we present a brief discussion of the physical scenario and our setup; in Section III we show and discuss our results for the thermodynamical quantities computed; and section IV contains our final remarks.

II. PHYSICAL SCENARIO AND SETUP

The phase diagram of QCD in the temperature versus isospin chemical potential plane is illustrated in Fig. [1], which should be seen as a cartoon. Along the temperature axis ($\mu_I = 0$) there is no phase transition, according to lattice calculations at physical quark masses [27]. At high isospin density, for values of $\mu_I$ above the pion mass $m_\pi$, pion condensation takes place for not too large temperatures. At very high isospin density a Fermi liquid with Cooper pairing is formed as a consequence of an attractive interaction between quarks in the isospin channel [4]. In contrast to the temperature versus baryon chemical potential ($\mu_B$) plane, there is a first-order deconfinement phase transition for large $\mu_I$ within the confined phase, as indicated by the green line in Fig. [1]. The authors of Ref. [5] conjecture that the phase transition line ends at a second-order point [2]. According to Ref. [14], the chiral phase transition is located along the purple line in Fig. [1].

1 Other investigations suggest different scenarios concerning the existence of this critical point [28].
Lattice calculations of Ref. [26] were run at nonzero \( \mu_I \) and at a fixed temperature of \( T = 20 \text{ MeV} \). The values of \( \mu_I \) covered in the simulations are indicated by the horizontal red line in Fig. [1]. Our perturbative calculations were performed for values of the isospin chemical potential which are represented by the blue solid line, at \( T = 0 \). This difference should not be significant given the comparatively large values of \( \mu_I \), as was verified a posteriori.

The energy scale of the (de)confinement transition was computed in Ref. [28] using an effective model description and found to be quite low, \( \Lambda_{\text{Con}} \approx 15–50 \text{ MeV} \). Numerical values for the (de)confinement scale were also computed in Refs. [7 13 14].

The phenomenon of pairing mentioned above should not be relevant for our perturbative study, in the same fashion that happens at nonzero (large) baryon chemical potential. The gap \( \Delta \) is exponentially suppressed for small values of \( g \), in the domain of validity of perturbation theory [11 29],

\[
\Delta = h |\mu_I| g^{-5} e^{-c/g},
\]

where \( c = 3\pi^2/2 \) and \( g = g(\mu_I) \) is the running coupling. We expect that the corresponding gap for nonzero isospin chemical potential will stay below \( \Delta \sim 300–400 \text{ MeV} \) and hence will give a subleading contribution to the thermodynamic potential \( \sim \mu_I^2 \Delta^2 \) [30].

Since the lattice calculations (red line in Fig. [1]) might cross the deconfinement transition (green line) as conjectured in Ref. [28], one can expect that perturbative calculations could provide a reasonable description of lattice results for large enough values of \( \mu_I \). With the help of Fig. 2 in Ref. [28], a quantitative statement about the scale of \( \mu_I \) at which the deconfined phase appears can be made: for \( \mu_I \approx 4 \text{ GeV} \) the deconfinement phase transition line crosses \( T = 20 \text{ MeV} \), the value used in the lattice simulations of Ref. [26] to which we compare our findings.

For \( T = 0 \) the expressions for the thermodynamic potential are available in analytic form up to \( \mathcal{O}(a_s^2) \). The one massive flavor contribution (leading and next-to-leading order) in the \( \overline{\text{MS}} \) scheme is given by (see, e.g. Refs. [31 33])

\[
\Omega^{(0)} = -\frac{N_C}{12\pi^2} \left[ \mu u \left( \mu^2 - \frac{5}{2} m^2 \right) + \frac{3}{2} m^4 \ln \left( \frac{\mu + u}{m} \right) \right],
\]

\[
\Omega^{(1)} = \frac{\alpha_s N_G}{16\pi^2} \left[ 3 m^2 \ln \left( \frac{\mu + u}{m} \right) - \mu u \right]^2 - 2 u^4
\]

\[
+ m^2 \left[ 6 \ln \left( \frac{\Lambda}{m} \right) + 4 \left( \mu u - m^2 \ln \left( \frac{\mu + u}{m} \right) \right) \right],
\]

where \( u \equiv \sqrt{\mu^2 - m^2} \) and \( N_C \) and \( N_G \) are the numbers of colors and gluons, respectively. For calculations with 2+1 massive quark flavors we introduce the isospin chemical potential in the following way:

\[
\mu_I = \mu_u - \mu_d, \quad \mu_q = \frac{\mu_u + \mu_d}{2}, \quad \mu_u = \mu_q + \frac{1}{2} \mu_I, \quad \mu_d = \mu_q - \frac{1}{2} \mu_I,
\]

\[
\mu_s = 0,
\]

where \( \mu_q \) is the quark chemical potential. We assume \( \mu_q = 0 \) in what follows.

### III. RESULTS

In order to compare our results with those from lattice simulations presented in Ref. [26], we adjusted our parameters accordingly. The strange quark chemical potential \( \mu_s \) is chosen to be zero, and \( m/s = 390 \text{ MeV} \), which corresponds to light quark masses \( m_{u/d} \) and a strange quark mass \( m_s \) given by

\[
m_{u/d} = 35 \text{ MeV} \quad \text{and} \quad m_s = 875 \text{ MeV} \quad ,
\]

as extracted from the GOR-relation [34]. Since \( \mu_s = 0 \), the strange quark plays no role in our analysis.

Our calculations implement a running coupling \( \alpha_s [35] \)

\[
\alpha_s(\Lambda) = \frac{4\pi}{\beta_0 L} \left[ 1 - \frac{2 \beta_1 \ln L}{\beta_0^2} \right],
\]

where \( L = 2 \ln(\Lambda/\Lambda_{\text{MS}}) \), \( \beta_0 = 11 - 2 N_f/3 \) and \( \beta_1 = 51 - 19 N_f/3 \). The scale \( \Lambda_{\text{MS}} \) and is fixed by requiring \( \alpha_s \approx 0.3 \) at \( \Lambda = 2 \text{ GeV} \) [36] and one obtains \( \Lambda_{\text{MS}} \approx 380 \text{ MeV} \). See also Ref. [31] for details. With these conventions, the only freedom left is the choice of the renormalization scale \( \Lambda \), which is set to \( \Lambda = 2 \mu_I \) in all of our numerical simulations.
FIG. 3. Comparison of the isospin chemical potential versus the isospin density with lattice results from Ref. [26].

From the thermodynamic potential, Eqs. (2) and (3), we have full access to all thermodynamical quantities, such as the pressure

\[ \Omega = -pV , \quad (7) \]

the isospin density \( \rho_I \)

\[ \rho_I = \frac{\partial p}{\partial \mu_I} , \quad (8) \]

and the energy density \( \varepsilon \) (for \( T = 0 \))

\[ \varepsilon = \frac{\partial p}{\partial \mu_I} \mu_I - p . \quad (9) \]

In Figs. 2 and 3, we compare our results with lattice data from Ref. [26]. In Fig. 2, the ratio of energy density to (isospin density)\(^{4/3}\) is plotted against the isospin density. One can see that for increasing isospin density the two curves approach each other, as expected from asymptotic freedom, although perturbation theory systematically overestimates this quantity within the range of available lattice data extracted from Ref. [26]. We stress that the density dependence with a power of \( 4/3 \) is characteristic for an ultrarelativistic Fermi gas, the asymptotic limit at high chemical potentials. Note that an isospin density of roughly 9 fm\(^{-3}\) corresponds to a value of \( \mu_I = 2 \) GeV.

In Fig. 3, the isospin chemical potential (subtracted by and normalized by the pion mass) is displayed versus the isospin density. The results from pQCD agree well with those that correspond to a band of lattice results extracted from Ref. [26] for values of the isospin chemical potential larger than about a few times the pion mass.

In Fig. 4, we exhibit the energy density normalized by the Stefan-Boltzmann (SB) form versus \( \mu_I/m_\pi \). Lattice results from Ref. [26] are shown with regard to the SB limit for a gas of quarks at zero temperature and high chemical potentials and hence also the SB limit for pQCD calculations.

\[ \varepsilon_{SB} = \frac{N_fN_c}{4\pi^2} \mu_I^4 . \quad (10) \]

In terms of quark degrees of freedom the SB limit is given as a function of the quark chemical potential

\[ \varepsilon_{SB} = \frac{N_fN_c}{4\pi^2} \mu^4 = \frac{N_fN_c}{4\pi^2} \mu_I^4 . \quad (11) \]

which gives via the relation \( \mu = \frac{1}{2} \mu_I \) a factor 16 difference in the corresponding SB limits. The latter one would be the limit for a gas of quarks at zero temperature and high chemical potentials and hence also the SB limit for pQCD calculations.

One sees in Fig. 4 that for \( \mu_I > 2m_\pi \) the pQCD results are compatible with the ones from the lattice. The peak at \( \mu_I = m_\pi \) can not be reproduced since it is caused by the pion condensate which is not captured by perturbation theory. Simulations that are based on chiral perturbation theory (\( \chi \)PT) are indeed able to calculate this maximum [37]. By maximizing the static chiral Lagrangian density the authors derive an analytic expression for the normalized energy density at the peak at leading-order. In general, lattice data is well reproduced by chiral perturbation theory (\( \chi \)PT) at leading-order for low densities, \( \mu_I < 2m_\pi \). However, for \( \mu_I > 2m_\pi \) the results of chiral perturbation theory asymptotically approaches zero as only pion degrees of freedom are incorporated. This is in contrast to the lattice data which reaches at asymptotically high isospin chemical potentials our results from pQCD which is based on quark degrees of freedom. In Fig. 5 the same data of Fig. 4 is shown with regard to the SB limit for a gas of quarks, i.e. rescaled by a factor of 16 which appears when \( \mu = \frac{1}{2} \mu_I \). The SB limit for 2 flavors (horizontal line) is also sketched in Fig. 5 because the strange quark is not
IV. SUMMARY

We investigated thermodynamic properties of massive cold quark matter at zero temperature and baryon chemical potential and non-vanishing isospin density at next-to-leading order in perturbation theory, and compared our results with recent lattice data.

The ratio of energy density to (isospin density)$^{4/3}$ versus isospin density shows that lattice data and our pQCD results get closer for high densities. Both seem to follow a $\rho_f^{4/3}$ scaling at high densities, which agrees with the limit for an ultra-relativistic degenerate Fermi gas. The isospin chemical potential plotted against the isospin density shows that the pQCD results and lattice results converge for values of $\mu_I \gtrsim 3m_\pi$. This is also true for the comparison of the normalized energy density as a function of the isospin chemical potential. The normalized energy density is essentially constant in the high-density limit, as expected.

We also verified that the energy density from the pQCD calculation is not too far from the Stefan-Boltzmann limit for two flavors since the strange quark does not appear in the dense medium under consideration. Furthermore, the deviations from an ideal equation of state are small.

In summary, the results from pQCD seem to be close to the lattice data already for values of $\mu_I \gtrsim 3m_\pi$, even in the region of pion condensate. It seems that the effect from the gap is suppressed for small values of the coupling constant, as anticipated, and gives a small contribution to the thermodynamic potential which is then dictated at high chemical potentials by a nearly free gas of quarks.

ACKNOWLEDGMENTS

The authors want to thank Rainer Stiele, Lorenz von Smekal, Nils Strodthoff and William Detmold for fruitful discussions. ESF is grateful for the kind hospitality of the ITP group at Frankfurt University, where this work has been initiated. TG is supported by the Helmholtz International Center for FAIR and the Helmholtz Graduate School HGS-HIRe. The work of ESF is partially supported by CAPES, CNPq and FAPERJ.

Finally, in Fig. 6 we plot the equation of state to exhibit the deviations from ideality, i.e. $\varepsilon = 3p$. The equation of state follows closely the one for an ideal ultrarelativistic gas.
