Abstract

In this paper we explore fundamental problems in randomized communication complexity such as computing Set Intersection on sets of size $k$ and Equality Testing between vectors of length $k$. Brody et al. \cite{BCK16} and Sağlam and Tardos \cite{ST13} showed that for these types of problems, one can achieve optimal communication volume of $O(k)$ bits, with a randomized protocol that takes $O(\log \ast k)$ rounds. They also proved \cite{BCK16,ST13} that this is one point along the optimal round-communication tradeoff curve.

Aside from rounds and communication volume, there is a third parameter of interest, namely the error probability $p_{err}$. It is straightforward to show that protocols for Set Intersection or Equality Testing need to send $\Omega(k + \log p_{err}^{-1})$ bits. Is it possible to simultaneously achieve optimality in all three parameters, namely $O(k + \log p_{err}^{-1})$ communication and $O(\log \ast k)$ rounds?

In this paper we prove that there is no universally optimal algorithm, and complement the existing round-communication tradeoffs \cite{BCK16,ST13} with a new tradeoff between rounds, communication, and probability of error. In particular:

- Any protocol for solving Multiple Equality Testing in $r$ rounds with failure probability $p_{err} = 2^{-E}$ has communication volume $\Omega(Ek^{1/r})$.
- There exists a protocol for solving Multiple Equality Testing in $r + \log \ast (k/E)$ rounds with $O(k + rEk^{1/r})$ communication, thereby essentially matching our lower bound and that of \cite{BCK16,ST13}.
- Lower bounds on Equality Testing extend to Set Intersection, for every $r, k, p_{err}$ (which is trivial); in the reverse direction, upper bounds on Equality Testing for $r, k, p_{err}$ imply similar upper bounds on Set Intersection with parameters $r + 1, k, p_{err}$.

Our original motivation for considering $p_{err}$ as an independent parameter came from the problem of enumerating triangles in distributed (CONGEST) networks having maximum degree $\Delta$. We prove that this problem can be solved in $O(\Delta/\log n + \log \log \Delta)$ time with high probability $1 - 1/poly(n)$. This beats the trivial (deterministic) $O(\Delta)$-time algorithm and is superior to the $\tilde{O}(n^{1/3})$ algorithm of \cite{CPZ19,CS19} when $\Delta = \tilde{O}(n^{1/3})$.

1 Introduction

Communication Complexity was defined by Yao [Yao79] in 1979 and has become an indispensable tool for proving lower bounds in models of computation in which the notions of parties and communication are not direct. See, e.g., books and monographs [Ron16, Ry, KN77] and surveys [CP10, Lov89] on the subject. In this paper we consider some of the most fundamental and well-studied problems in this model, such as \textbf{SetDisjointness}, \textbf{SetIntersection}, \textbf{ExistsEqual}, and \textbf{EqualityTesting}. Let us briefly define these problems formally since the terminology is not completely standard.

\textbf{SetDisjointness and SetIntersection.} In the \textbf{SetDisjointness} problem Alice and Bob receive sets \(A \subset U\) and \(B \subset U\) where \(|A|, |B| \leq k\) and must determine whether \(A \cap B = \emptyset\). Define \(\text{SetDisj}(k, r, p_{err})\) to be the minimum communication complexity of an \(r\)-round randomized protocol for this problem that errs with probability at most \(p_{err}\). We can assume that \(|U| = O(k^2/p_{err})\) without loss of generality.\(^{1}\) The input to the \textbf{SetIntersection} problem is the same, except that the parties must report the entire set \(A \cap B\). Define \(\text{SetInt}(k, r, p_{err})\) to be the minimum communication complexity of an \(r\)-round protocol for \textbf{SetIntersection}.

\textbf{EqualityTesting and ExistsEqual.} In the \textbf{EqualityTesting} problem Alice and Bob hold vectors \(x \in U^k\) and \(y \in U^k\) and must determine, for each index \(i \in [k]\), whether \(x_i = y_i\) or \(x_i \neq y_i\). A potentially easier version of the problem, \textbf{ExistsEqual}, is to determine if there exists at least one index \(i \in [k]\) for which \(x_i = y_i\). Define \(\text{Eq}(k, r, p_{err})\) to be the randomized communication complexity of any \(r\)-round protocol for \textbf{EqualityTesting} that errs with probability \(p_{err}\), and \(\exists\text{Eq}(k, r, p_{err})\) the corresponding complexity of \textbf{ExistsEqual}. Once again, we can assume that \(|U| = O(k/p_{err})\) without loss of generality.

The deterministic communication complexity of these problems is well understood [KN97, FKNN95, BCK+16, ST13, KS92], so we consider randomized complexity exclusively. Although these problems are well studied [HW07, FKNN95, BCK+16, ST13, KS92], most prior work has focused on the relationship between round complexity and communication volume, and has paid comparatively little attention to the role of \(p_{err}\).

\textbf{History.} Hästad and Wigderson [HW07] gave an \(O(\log k)\)-round protocol for \textbf{SetDisjointness} in which Alice and Bob communicate \(O(k)\) bits, which matched an \(\Omega(k)\) lower bound of Kalyanasundaram and Schnitger [KS92]; see also [Raz92, BGMdW13, DKS12]. Feder et al. [FKNN95] proved that \textbf{EqualityTesting} can be solved with \(O(k)\) communication by an \(O(\sqrt{k})\)-round protocol that errs with probability \(\exp(-\sqrt{k})\). Improving [HW07], Sağlam and Tardos [ST13] gave an \(r\)-round protocol for \textbf{SetDisjointness} that uses \(O(k \log^r k)\) communication, where \(\log^r k\) is the \(r\)-fold iterated logarithm function. For \(r = \log^* k\) the error probability of this algorithm is \(\exp(-\sqrt{k})\), coincidentally matching [FKNN95]. In independent work, Brody et al. [BCK+16] gave \(r\)-round and \(O(r)\)-round protocols for \textbf{ExistsEqual} and \textbf{SetIntersection}, respectively, that use \(O(k \log^r k)\) communication and err with probability \(1/poly(k)\). Sağlam and Tardos [ST13] and Brody et al. [BCK+16] also proved that for

\(^{1}\)Before the first round of communication, pick a pairwise independent \(h : U \mapsto [O(k^2/p_{err})]\) and check whether \(h(A) \cap h(B) = \emptyset\) with error probability \(p_{err}/2\). Thus, having \textbf{SetDisj} depend additionally on \(|U|\) is somewhat redundant, at least when \(|U|\) is large.

\(^{2}\)When \(p_{err} = 0\), the deterministic complexity must be expressed in terms of \(k\) and \(|U|\).
| Problem                        | Commun. | Rounds       | Error Probability         | Ref.     |

Table 1: Upper and Lower bounds on SetDisjointness, SetIntersection, EqualityTesting, and ExistsEqual. Via trivial reductions, lower bounds on ExistsEqual extend to all four problems, and upper bounds on SetIntersection extend to all four problems. From Theorem 1 the upper bounds on SetIntersection and SetDisjointness follow from those of EqualityTesting and ExistsEqual, respectively, +1 round of communication. The log-star function is defined as $\log^*(x) = \min\{i : \log^{(i)}(x) \leq 1\}$, e.g., $\log^*(k/E) = 0$ if $E \geq k$.

ExistsEqual, this tradeoff between rounds and communication is optimal. Brody et al. [BCK+16] also introduced a randomized reduction from SetIntersection to EqualityTesting, which carries a probability of error that is only tolerable if $p_{\text{err}} > \exp(-\widetilde{O}(\sqrt{k}))$.

### 1.1 Contributions

First, we observe that a simple deterministic reduction shows that SetIntersection is essentially equivalent to EqualityTesting for any $p_{\text{err}}$, up to one round of communication, and SetDisjointness is essentially equivalent to ExistsEqual for any $p_{\text{err}}$. Theorem 1 is proved in Appendix A; it is inspired by the randomized reduction of Brody et al. [BCK+16].

**Theorem 1.** For any parameters $k \geq 1$, $r \geq 1$, and $p_{\text{err}} > 0$, it holds that

\[
\begin{align*}
\text{Eq}(k, r, p_{\text{err}}) & \leq \text{SetInt}(k, r, p_{\text{err}}), \\
\exists \text{Eq}(k, r, p_{\text{err}}) & \leq \text{SetDisj}(k, r, p_{\text{err}}), \\
\text{SetInt}(k, r + 1, p_{\text{err}}) & \leq \text{Eq}(k, r, p_{\text{err}}) + \zeta, \\
\text{SetDisj}(k, r + 1, p_{\text{err}}) & \leq \exists \text{Eq}(k, r, p_{\text{err}}) + \zeta,
\end{align*}
\]

where $\zeta = O(k + \log \log p_{\text{err}}^{-1})$.

---

The two proofs take quite different strategies: Sağlam and Tardos's applies to protocols with constant error probability whereas Brody et al.'s assumes $1/\text{poly}(k)$ error.
Second, we prove that in any of the four problems, it is impossible to simultaneously achieve communication volume \(O(k + \log p_{err}^{-1})\) in \(O(\log^* k)\) rounds for all \(k, p_{err}\). Specifically, if \(p_{err} = 2^{-E}\), any \(r\)-round protocol needs \(\Omega(Ek^{1/r})\) communication. In other words, if we insist on having \(O(k)\) communication and \(O(\log^* k)\) rounds, the smallest error probability that can be achieved is \(p_{err} = \exp(-k^{1-\Theta(1/\log^* k)})\). We complement this lower bound with an upper bound showing that in \(r + \log^*(k/E)\) rounds, we can solve \textit{EqualityTesting} with \(O(k + rEk^{1/r})\) communication. This matches our lower bound when \(E \geq k\) and \(r\) is constant, but is slightly suboptimal when \(r = \omega(1)\). We illustrate two ways to shave off this factor of \(r\). We give an \((r + \log^*(k/E))\)-round \textit{ExistsEqual} protocol that communicates \(O(k + Ek^{1/r})\) bits, as well as an \textit{EqualityTesting} protocol that communicates \(O(k + Ek^{1/r})\) bits, but with round complexity \(O(r + \log^*(k/E))\).

Our original interest in \textit{SetIntersection} came from distributed subgraph detection in \textsc{CONGEST} networks, which has garnered significant interest in recent years [CSI19, CPZ19, IG17, ACKL17, DKO14, KR18, FGKO18, CK18, GO18]. Izumi and LeGall [IG17] proved that triangle enumeration requires \(\Omega(n^{1/3}/\log n)\) rounds in the \textsc{CONGEST} model, and further showed that local triangle enumeration requires \(\Omega(\Delta/\log n)\) rounds in \textsc{CONGEST}, which can be as large as \(\Omega(n/\log n)\).

The most natural way to solve (local) triangle enumeration is, for every edge \(\{u, v\} \in E(G)\), to have \(u\) and \(v\) run a two-party \textsc{SetIntersection} protocol in which they compute \(N(u) \cap N(v)\), where \(N(u) = \{\text{ID}(x) \mid \{u, x\} \in E(G)\}\) and \(\text{ID}(x) \in \{0, 1\}^{O(\log n)}\) is \(x\)'s unique identifier. Any \(r\)-round protocol with communication volume \(O(\Delta)\) can be simulated in \textsc{CONGEST} in \(O(\Delta/\log n + r)\) rounds since the message size is \(O(\log n)\) bits. However, to guarantee a global probability of success at least \(1 - 1/\text{poly}(n)\), the failure probability of each \textsc{SetIntersection} instance must be \(p_{err} = 2^{-E}\), \(E = \Theta(\log n)\), which is independent of \(\Delta\). Our communication complexity lower bound suggests that to achieve this error probability, we would need \(\Omega((\Delta + E\Delta^{1/r})/\log n + r)\) \textsc{CONGEST} rounds, i.e., with \(r = \log \Delta\) we should not be able to do better than \(O(\Delta/\log n + \log \Delta)\). We prove that (local) triangle enumeration can actually be solved exponentially faster, in \(O(\Delta/\log n + \log \log \Delta)\) \textsc{CONGEST} rounds, without necessarily solving every \textsc{SetIntersection} instance.

**Organization.** The proof of Theorem 1 on the near-equivalence of \textsc{SetIntersection/SetDisjointness} and \textsc{EqualityTesting/ExistsEqual} appears in Appendix A. Section 2 reviews concepts from information theory and communication complexity. In Section 3 we present new lower bounds for both \textsc{EqualityTesting} and \textsc{ExistsEqual} that incorporate rounds, communication, and error probability. Section 4 presents nearly matching upper bounds for \textsc{EqualityTesting} and \textsc{ExistsEqual}, and Section 5 applies them to the distributed triangle enumeration problem. We conclude with some open problems in Section 6.

---

4In the \textsc{CONGEST} model there is a graph \(G = (V, E)\) whose vertices are identified with processors and whose edges represent bidirectional communication links. Each vertex \(v\) does not know \(G\), and is only initially aware of an \(O(\log n)\)-bit \(\text{ID}(v)\), \(\deg(v)\), and global parameters \(n = |V|\) and \(\Delta \geq \max_{u \in V} \deg(u)\). Communication proceeds in synchronized rounds; in each round, each processor can send a (different) \(O(\log n)\)-bit message to each of its neighbors.

5Every triangle (3-cycle) in \(G\) must be reported by some vertex.

6Every triangle in \(G\) must be reported by at least one of the three constituent vertices. Izumi and LeGall [IG17] only stated the \(\Omega(n/\log n)\) lower bound but it can also be expressed in terms of \(\Delta\).
2 Preliminaries

2.1 Notational Conventions

The set of positive integers at most \( t \) is denoted \([t]\). Random variables are typically written as capital letters (\( X, Y, M, \) etc.) and the values they take on are lower case (\( x, y, m, \) etc.). The letters \( p, q, \mu, \mathcal{D} \) are reserved for probability mass functions (p.m.f.). E.g., \( \mathcal{D}(x) \) denotes the probability that \( X = x \) whenever \( X \sim \mathcal{D} \). The support \( \text{supp}(\mathcal{D}) \) of a distribution \( \mathcal{D} \) is the set of all \( x \) for which \( \mathcal{D}(x) > 0 \). If \( \mathcal{X} \subseteq \text{supp}(\mathcal{D}), \mathcal{D}(\mathcal{X}) = \sum_{x \in \mathcal{X}} \mathcal{D}(x) \).

Many of our random variables are vectors. If \( x \) is a \( k \)-dimensional vector and \( I \subseteq [k], x_I \) is the projection of \( x \) onto the coordinates in \( I \) and \( x_i \) is short for \( x_{\{i\}} \). Similarly, if \( \mathcal{D} \) is the p.m.f. of a \( k \)-dimensional random variable, \( \mathcal{D}_I \) is the marginal distribution of \( \mathcal{D} \) on the index set \( I \subseteq [k] \).

Throughout the paper, \( \log \) and \( \exp \) are the base-2 logarithm and exponential functions, and \( \log^{(r)} \) and \( \exp^{(r)} \) their \( r \)-fold iterated versions:

\[
\log^{(0)}(x) = \exp^{(0)}(x) = x, \quad \log^{(r)}(x) = \log(\log^{(r-1)}(x)), \quad \exp^{(r)}(x) = \exp(\exp^{(r-1)}(x)).
\]

The log-star function is defined to be \( \log^*(x) = \min\{r \mid \log^{(r)}(x) \leq 1\} \). In particular, \( \log^*(x) = 0 \) if \( x \leq 1 \).

2.2 Information Theory

The most fundamental concept in information theory is Shannon entropy. The Shannon entropy of a discrete random variable \( X \) is defined as

\[
H(X) = - \sum_{x \in \text{supp}(X)} \Pr[X = x] \log \Pr[X = x].
\]

Since there may be cases in which different distributions are defined for the “same” random variable, we use \( H(p) \) in place of \( H(X) \) if \( X \) is drawn from a p.m.f. \( p \). We also write \( H(\alpha), \alpha \in (0, 1) \), to be the entropy of a Bernoulli random variable with success probability \( \alpha \). In general, we freely use a random variable and its p.m.f. interchangeably.

The joint entropy \( H(X, Y) \) of two random variables \( X \) and \( Y \) is simply

\[
H(X, Y) = - \sum_{x \in \text{supp}(X)} \sum_{y \in \text{supp}(Y)} \Pr[X = x \land Y = y] \log \Pr[X = x \land Y = y].
\]

This notion can be easily extended to cases of more than two random variables. Here, we state a well known fact about joint entropy.

\textbf{Fact 2.1.} For any random variables \( X_1, X_2, \ldots, X_n \), their joint entropy is at most the sum of their individual entropies, i.e., \( H(X_1, X_2, \ldots, X_n) \leq \sum_{i=1}^{n} H(X_i) \).

The conditional entropy of \( Y \) conditioned on another random variable \( X \), denoted \( H(Y \mid X) \), measures the expected amount of extra information required to fully describe \( Y \) if \( X \) is known. It is defined to be

\[
H(Y \mid X) = H(X, Y) - H(X).
\]
Finally, the mutual information $I(X;Y)$ between two random variables $X$ and $Y$ quantifies the amount of information that is revealed about one random variable through knowing the other:

$$I(X;Y) = H(X) - H(X|Y) = H(X) + \sum_{y \in \text{supp}(Y)} \Pr[Y = y] \sum_{x \in \text{supp}(X)} \Pr[X = x | Y = y] \log \Pr[X = x | Y = y].$$

### 2.3 Communication Complexity

Let $f(x,y)$ be a function over domain $\mathcal{X} \times \mathcal{Y}$, and consider any two-party communication protocol $Q(x,y)$ that computes $f(x,y)$, where one party holds $x$ and the other holds $y$. The transcript of $Q$ on $(x,y)$ is defined to be the concatenation of all messages exchanged by the two parties, in order, as they execute on input $(x,y)$. The communication cost of $Q$ is the maximum transcript length produced by $Q$ over all possible inputs.

Let $Q_d$ be a deterministic protocol for $f$ and suppose $\mu$ is a distribution over $\mathcal{X} \times \mathcal{Y}$. The distributional error probability of $Q_d$ with respect to $\mu$ is the probability $\Pr_{(x,y) \sim \mu}[Q_d(x,y) \neq f(x,y)]$. For any $0 < \epsilon < 1$, the $(\mu, \epsilon)$-distributional deterministic communication complexity of the function $f$ is the minimum communication cost of any protocol $Q_d$ that has distributional error probability at most $\epsilon$ with respect to the distribution $\mu$.

A randomized protocol $Q_r(x,y,w)$ also takes a public random string $w \sim \mathcal{W}$ as input. The error probability of $Q_r$ is calculated as $\max_{(x,y) \in \mathcal{X} \times \mathcal{Y}} \Pr_{(w) \sim \mathcal{W}}[Q_r(x,y,w) \neq f(x,y)]$. The $\epsilon$-randomized communication complexity of $f$ is the minimum communication cost of $Q_r$ over all protocols $Q_r$ with error probability at most $\epsilon$.

Yao’s minimax principle [Yao77] is a common starting point for lower bound proofs in randomized communication complexity. The easy direction of Yao’s minimax principle states that the communication cost of the best deterministic protocol specific to any particular distribution is at most the communication cost of any randomized protocol on its worst case input.

**Lemma 2.2** (Yao’s minimax principle [Yao77]). Let $f : \mathcal{X} \times \mathcal{Y} \mapsto \mathcal{Z}$ be the function to be computed. Let $D_{\mu,\epsilon}(f)$ be the $(\mu, \epsilon)$-distributional deterministic communication complexity of $f$, and let $R_\epsilon(f)$ be the $\epsilon$-randomized communication complexity of $f$. Then for any $0 < \epsilon < 1/2$,

$$\max_{\mu} D_{\mu,2\epsilon}(f) \leq 2R_\epsilon(f).$$

Therefore, to show a lower bound on the $\epsilon$-randomized communication complexity of a function $f$, it suffices to find a hard distribution $\mu$ on the input set and prove a lower bound for the communication cost of any deterministic protocol that has distributional error probability at most $2\epsilon$ with respect to $\mu$.

### 3 Lower Bounds on ExistsEqual and EqualityTesting

In this section we prove lower bounds on EqualityTesting and ExistsEqual. Theorem 2 obviously follows directly from Theorem 3 but we prove them in that order nonetheless because Theorem 2 is a bit simpler.
**Theorem 2.** Any $r$-round randomized protocol for **EqualityTesting** on vectors of length $k$ that errs with probability $p_{err} = 2^{-E}$ requires at least $\Omega(Ek^{1/r})$ bits of communication.

**Theorem 3.** Any $r$-round randomized protocol for **ExistsEqual** on vectors of length $k$ that errs with probability $p_{err} = 2^{-E}$ requires at least $\Omega(Ek^{1/r})$ bits of communication.

Without any constraint on the number of rounds, **EqualityTesting** trivially requires $\Omega(k)$ communication. **ExistsEqual** also requires $\Omega(k)$ communication, through a small modification to the **SetDisjointness** lower bounds [KS92, Raz92]. Even when $k = 1$, we need at least $\Omega(E)$ communication to solve **EqualityTesting/ExistsEqual** with error probability $2^{-E}$ [KN97]. Thus, we can assume that $E = \Omega(k^{1-1/r})$, $k^{1/r} = \Omega(1)$, and hence $r = O(\log k)$. For example, some calculations later in our proof hold when $r \leq (\log k)/6$. When proving Theorem 3, we will further assume $E = \Omega(\log k)$ when $r = 1$, which is reasonable because of Sağlam and Tardos’ $\Omega(k\log^{(r)} k) = \Omega(k\log k)$ lower bound [ST13].

### 3.1 Structure of the Proof

We consider deterministic strategies for **ExistsEqual/EqualityTesting** when Alice and Bob pick their input vectors independently from the uniform distribution on $[t]^k$, where $t = 2^E$ and $c = 1/2$. Although the probability of seeing a collision in any particular coordinate is small, it is still much larger than the tolerable error probability (since $c < 1$), so it is incorrect to declare “not equal in every coordinate” without performing any communication.

We suppose, for the purpose of obtaining a contradiction, that there is a protocol for **EqualityTesting** with error probability $2^{-E}$ and communication complexity $c'Ek^{1/r}$, where $c' = c/100$. The length of the $j$th message is $l_j$, which could depend on the parameters $(E, r, k, \text{etc.})$ and possibly in some complicated way on the transcript of the protocol before round $j$.

Our proof must necessarily consider transcripts of the protocol that are extremely unlikely (occurring with probability close to $2^{-E}$) and also maintain a high level of uncertainty about which coordinates of Alice’s and Bob’s vectors might be equal. Consider the first message. Alice picks her input vector $x \in [t]^k$, which dictates the first message $m_1$. Suppose, for simplicity, that it betrays exactly $l_1/k < c'Ek^{1/r-1}$ bits of information per coordinate of $x$. Before Bob can respond with a message $m_2$ he must commit to his input, say $y$. Most values of $y$ result in “good” outcomes: nearly all non-equal coordinates get detected immediately and the effective size of the problem is dramatically reduced. We are not interested in these values of $y$, only very “bad” values. Let $I_1$ be the first $k^{1-1/r}$ coordinates (or, more generally, $k^{1-1/r}$ coordinates that $m_1$ revealed below-average information about). With probability about $(2-c'Ek^{1/r-1})^{|I_1|} = 2^{-c'E}$, Bob picks an input $y$ that is completely consistent with Alice’s on $I_1$, i.e., as far as he can tell $y_i = x_i$ for every $i \in I_1$. Rather than sample $y$ uniformly from $[t]^k$, we sample it from a “hybrid” distribution: $y_i$ is sampled from the same distribution that $m_1$ revealed about $x_i$ (forcing the above event to happen with probability 1), and $y_{[k]\setminus I_1}$ is sampled from Bob’s former distribution (in this case, the uniform distribution on $[t]^{k-|I_1|}$), conditioned on the value of $y_{I_1}$.

This process continues round by round. Bob’s message $m_2$ betrays at most $l_2/|I_1| < c'Ek^{2/r-1}$ bits of information on each coordinate of $y_{I_1}$, and there must be an index set $I_2 \subseteq I_1$ with $|I_2| = l_2/|I_1|$.

---

7In the context of **ExistsEqual/EqualityTesting**, it is natural to think about uniform-length messages, i.e., $l_j < c'Ek^{1/r}$, or lengths that decay according to some convergent series, e.g., $l_j \propto c'Ek^{1/r}/2^j$ or $l_j \propto c'Ek^{1/r}/j^2$. 

---
\(k^{1-2/r}\) such that, with probability around \(2^{-cE}\), it is completely consistent that \(x_{I_2} = y_{I_2}\). Alice resamples her input so that this (rare) event occurs with probability 1, generates \(m_3\), and continues.

At the end of this process \(|I_r| = k^{1-r/r} = 1\), and yet Alice and Bob have revealed less than the full \(cE\) bits of entropy about \(x_{I_r}\) and \(y_{I_r}\). Regardless of whether they report “equal” or “not equal” (on \(I_r\)), they are wrong with probability greater than \(2^{-E}\). Are we done? Absolutely not! The problem is that this strange process for sampling a possible transcript of the protocol might itself only find transcripts that occur with probability \(\ll 2^{-E}\), making any conclusions we make about its (probability of) correctness moot. Generally speaking, we need to show that Alice’s and Bob’s actions are consistent with events that occur with probability \(\gg 2^{-E}\).

Let us first make every step of the above process a bit more formal. It is helpful to think about Alice’s and Bob’s inputs not being fixed vectors selected at time zero, but simply distributions over vectors that change as messages progressively reveal more information about them.

- Before the \(j\)th round of communication, the sender of the \(j\)th message’s input is drawn from a discrete distribution \(\hat{D}^{(j-1)}\) over \([t]^k\). The receiver of the \(j\)th message’s input is drawn from the distribution \(D^{(j-1)}\). For example, when \(j = 1\), if Alice speaks first then her initial distribution, \(\hat{D}^{(0)}\), and Bob’s initial distribution, \(D^{(0)}\), are both uniform over \([t]^k\).

- Before the \(j\)th round of communication both parties are aware of an index set \(I_{j-1}\) such that, informally, (i) the distributions \(D_{I_{j-1}}^{(j-1)}\) and \(\hat{D}_{I_{j-1}}^{(j-1)}\) are very similar, and in particular, it is consistent that their inputs are identical on \(I_{j-1}\), and (ii) the messages transmitted so far reveal “average” or below-average information about these coordinates. For example, \(I_0 = [k]\) and it is consistent with the empty transcript that Alice’s and Bob’s inputs are identical on every coordinate.

- The \(j\)th message is a random variable \(M_j \in \{0,1\}^j\). In order to pick an \(m_j\) according to the right distribution, the sender picks an input \(x \sim \hat{D}^{(j-1)}\) which, together with the history \(m_1, \ldots, m_{j-1}\), determines \(m_j\). The sender transmits \(m_j\) to the receiver and promptly forgets \(x\). The sender’s new distribution (i.e., \(\hat{D}^{(j-1)}\), conditioned on \(M_j = m_j\)) is called \(D^{(j)}\).

- The distribution \(D^{(j)}\) may reveal information about the coordinates \(I_{j-1}\) in an irregular fashion. We find a subset \(I_j \subset I_{j-1}\) of coordinates, \(|I_j| = k^{1-j/r}\), for which the amount of information revealed by \(D^{(j)}_{I_j}\) is at most average. The receiver of \(m_j\) changes his input distribution to \(\hat{D}^{(j)}\), which is defined so that it basically agrees with \(D^{(j)}_{I_j}\) and the marginal distribution \(\hat{D}^{(j)}_{[k] \setminus I_j}\) conditioned on the value selected by \(D^{(j)}_{I_j}\), is identical to \(D^{(j)}_{[k] \setminus I_j}\).

- The reason \(D^{(j)}_{I_j}\) and \(\hat{D}^{(j)}_{I_j}\) are not identical is due to two filtering steps. To generate \(\hat{D}^{(j)}\), we remove points from the support that have tiny (but non-zero) probability, which may be too close to the error probability. Intuitively these rare events necessarily represent a small fraction of the probability mass. Second, we remove points from the support if the ratio of their probability occurring under \(D^{(j)}\) over \(D^{(j-1)}\) is too high. Intuitively, we want to conclude that if there is a high probability of an error occurring under \(D^{(j)}\) then the probability is also high under \(D^{(j-1)}\) (and by unrolling this further, under \(D^{(0)}\)). This argument only works if the ratios are what we would expect, given how much information is being revealed about these coordinates by \(m_j\). As a result of these two filtering steps, \(\mathcal{D}^{(j)}_{I_j}(x_{I_j})\) and \(\hat{\mathcal{D}}^{(j)}_{I_j}(x_{I_j})\) differ by at most a constant factor, for any particular vector \(x_{I_j} \in [t]^{|I_j|}\).
3.2 A Lower Bound on Equality Testing

We begin with two general lemmas about discrete probability distributions that play an important role in our proof.

Roughly speaking, Lemma 3.1 captures and generalizes the following intuition: Suppose $p$ is a high entropy distribution on some universe $U$ and $q$ is obtained from $p$ by conditioning on an event $X \subseteq U$ such that $p(X)$ is large, say some constant like $1/4$. If $p$’s entropy is close to $\log |U|$, then $q$’s entropy should not be much smaller than that of $p$. As our proof goes on round by round, we will constantly throw away part of the input distribution’s support to meet certain conditions. It is Lemma 3.1 that guarantees that the input distributions continue to have relatively high entropy.

Lemma 3.2 comes into play because the error probability will be calculated backward in a round-by-round manner. Suppose the old distribution ($p$) has no extremely low probability point and the new distribution ($q$) has almost full entropy. Lemma 3.2 provides us with a useful tool to transfer a lower bound on the probability of any event w.r.t. $q$ to a lower bound on the same event w.r.t. $p$.

Lemma 3.1. Let $p$ and $q$ be distributions defined on a universe of size $2^s$. Suppose both of the following properties are satisfied:

1. The entropy of $p$ is $H(p) \geq s - g$, where $0 \leq g \leq s$;
2. There exists $0 < \alpha < 1$ such that $q(x) \leq p(x)/\alpha$ holds for every value $x \in \text{supp}(q)$.

The entropy of $q$ is lower bounded by:

$$H(q) \geq s - g/\alpha - H(\alpha)/\alpha.$$ 

Proof. Let $X$ be the whole universe. From our assumptions, the entropy of $q$ can be lower bounded as follows.

$$H(q) = \sum_{x \in X} q(x) \log \frac{1}{q(x)} \quad \text{Defn. of } H(q).$$

$$= \frac{1}{\alpha} \sum_{x \in X} \alpha q(x) \log \frac{1}{\alpha q(x)} + \log \alpha \quad \text{Since } \sum_{x \in X} q(x) = 1.$$

$$\geq \frac{1}{\alpha} \sum_{x \in X} \left[ p(x) \log \frac{1}{p(x)} - (p(x) - \alpha q(x)) \log \frac{1}{p(x) - \alpha q(x)} \right] + \log \alpha \quad \text{Assumption 2}.$$

The previous step follows from Assumption 2 and the fact that $x \log x^{-1} + y \log y^{-1} \geq (x+y) \log (x+y)^{-1}$ for any $x, y \geq 0$. Continuing,

$$\geq \frac{1}{\alpha} \left[ s - g - \sum_{x \in X} (p(x) - \alpha q(x)) \log \frac{1}{p(x) - \alpha q(x)} \right] + \log \alpha \quad \text{Assumption 1}.$$

$$\geq \frac{1}{\alpha} \left[ s - g - (1 - \alpha) \log \frac{2^s}{1 - \alpha} \right] + \log \alpha \quad \text{Concavity of logarithm}.$$

$$= s - \frac{g}{\alpha} + \frac{1 - \alpha}{\alpha} \log (1 - \alpha) + \log \alpha = s - \frac{g}{\alpha} - \frac{H(\alpha)}{\alpha}.$$
Lemma 3.2. Let $p$ and $q$ be distributions defined on a universe of size $2^s$. Suppose both of the following properties are satisfied:

1. The entropy of $q$ is $H(q) \geq s - g_1$, where $0 \leq g_1 \leq s$;
2. There exists $g_2 \geq 0$ such that $p(x) \geq 2^{-s-g_2}$ holds for every value $x \in \text{supp}(q)$.

Then, for any $0 < \alpha < 1$,

$$\Pr_{x \sim q} \left[ \frac{q(x)}{p(x)} > 2^{g_1/\alpha + g_2 - (1-\alpha)\log(1-\alpha)/\alpha} \right] \leq \alpha.$$  

Proof. Let $\mathcal{X}_0 = \{x \in \text{supp}(q) \mid q(x)/p(x) \leq 2^{g_1/\alpha + g_2 - (1-\alpha)\log(1-\alpha)/\alpha}\}$ and $\mathcal{X}_1 = \text{supp}(q) \setminus \mathcal{X}_0$. Suppose, for the purpose of obtaining a contradiction, that the conclusion of the lemma is false, i.e., $q(\mathcal{X}_1) = \alpha_0$, for some $\alpha_0 > \alpha$. Notice that for each value $x \in \mathcal{X}_1$, Assumption 2 implies that

$$q(x) > p(x) : 2^{g_1/\alpha + g_2 - (1-\alpha)\log(1-\alpha)/\alpha} \geq 2^{-s+g_1/\alpha-(1-\alpha)\log(1-\alpha)/\alpha}. \quad (1)$$

Then we can upper bound the entropy of $q$ as follows.

$$H(q) = \sum_{x \in \mathcal{X}_0} q(x) \log \frac{1}{q(x)} + \sum_{x \in \mathcal{X}_1} q(x) \log \frac{1}{q(x)} \quad \text{Defn. of } H(q).$$

$$< \sum_{x \in \mathcal{X}_0} q(x) \log \frac{1}{q(x)} + \alpha_0 \left[ s - \frac{g_1}{\alpha} + \frac{1-\alpha}{\alpha} \log(1-\alpha) \right] \quad \text{Eqn. (1)}. $$

$$\leq (1 - \alpha_0) \log \frac{2^s}{1 - \alpha_0} + \alpha_0 \left[ s - \frac{g_1}{\alpha} + \frac{1-\alpha}{\alpha} \log(1-\alpha) \right] \quad \text{Concavity of logarithm}. $$

$$= s - \frac{\alpha_0}{\alpha} g_1 + \alpha_0 \left[ \frac{1-\alpha}{\alpha} \log(1-\alpha) - \frac{1-\alpha_0}{\alpha_0} \log(1-\alpha_0) \right]$$

$$< s - g_1,$$

where the last step follows from the monotonicity of $(1-\alpha)\log(1-\alpha)/\alpha$. This contradicts Assumption 1. \qed

We are now ready to begin the proof of Theorem 2 proper. Fix a round $j$ and a particular history $(m_1, \ldots, m_{j-1})$ up to round $j-1$. We let $\mu_j(m_j)$ denote the probability that the $j$th message is $m_j$, if the input to the sender is drawn from $\tilde{D}^{(j-1)}$. Define $\tilde{D}^{(j)}[m_j]$ to be the new input distribution of the sender after he commits to $m_j$. When $m_j$ is clear from context, it is denoted $\tilde{D}^{(j)}$. (The process for deriving $\tilde{D}^{(j)}$ from $D^{(j)}$ and $D^{(j-1)}$ on the receiver’s end will be explained in detail later.)

We will prove by induction that the following Invariant 3.3 holds for each $j \in [0,r]$, where the particular values of $I_j, D^{(j)}, \tilde{D}^{(j)}, l_1, \ldots, l_j$ depend on the transcript $m_1, \ldots, m_j$ that is sampled. In the base case, Invariant 3.3 clearly holds when $j = 0, I_0 = [k]$, and both $\tilde{D}^{(0)}, D^{(0)}$ are the uniform distribution over $[k]^k$.

Invariant 3.3. After round $j \in [0,r]$ the partial transcript is $m_1, \ldots, m_j$, which determines the values $\{l_j, \tilde{D}^{(j)}, D^{(j)}, l_j, I_j\}_{j' \leq j}$. The index set $I_j \subseteq [k]$ satisfies all of the following:

1. $|I_j| = k^{1-j/r}$.
2. Each value $x_{I_j} \in [k]|I_j|$ satisfies $\tilde{D}^{(j)}_{l_j}(x_{I_j}) \leq 4D^{(j)}_{l_j}(x_{I_j})$. 

10
3. Each nonempty subset $I' \subseteq I_j$ satisfies

$$H(\tilde{D}^{(j)}_{I_j} \mid I') \geq \left( cE - \sum_{u=1}^{j} \frac{16^{j-u+1}l_u}{k^{l-1-(u-1)/r}} - 22^j \right) |I'|.$$ 

In accordance with our informal discussion in Section 3.1, $I_j$ is a subset of indices on which both parties have learned little information about each other from the partial transcript $m_1, \ldots, m_j$. Invariant 3.3(2) ensures that the two parties draw their inputs after the $j$th round from similar distributions. Invariant 3.3(3) is the most important property. It says that the information revealed by $\tilde{D}^{(j)}$ about $I'$ is roughly what one would expect, given the message lengths $l_1, \ldots, l_j$. Note that the $u$th message conveys information about $|I_{u-1}| = k^{l-1-(u-1)/r}$ indices so the average information-per-index should be $l_u/k^{l-1-(u-1)/r}$. The factor $16^{j-u+1}$ and the extra term $22^j$ come from Lemma 3.1 which throws away part of the input distribution in each round, progressively distorting the distributions in minor ways.

To begin our induction, at round $j$ we find a large fraction of possible messages $m_j$ that reveal little information about the sender’s input, projected onto $I_{j-1}$. This is possible because the length of the message $l_j = |m_j|$ reflects an upper bound on the expected information gain. This idea is formalized in the following Lemma 3.4.

**Lemma 3.4.** Fix $j \in [1, r]$ and suppose Invariant 3.3 holds for $j-1$. Then there exists a subset of messages $\mathcal{M}_j$ with $\mu_j(\mathcal{M}_j) \geq 1/2$ such that each message $m_j \in \mathcal{M}_j$ satisfies

$$H(D^{(j)}_{I_{j-1}}[m_j]) \geq \left( cE - 2 \sum_{u=1}^{j} \frac{16^{j-u+1}l_u}{k^{l-1-(u-1)/r}} - 2 \cdot 22^{j-1} \right) |I_{j-1}|.$$ 

**Proof.** Let $\mathcal{M}_j$ contain all messages $m_j$ satisfying the above inequality and $\mathcal{M}_j^c$ be its complement. Suppose, for the purpose of obtaining a contradiction, that the conclusion of the lemma is not true, i.e., $\mu_j(\mathcal{M}_j^c) = \alpha > 1/2$. Then the entropy of $\tilde{D}^{(j-1)}_{I_{j-1}}$ can be upper bounded as follows.

$$H(\tilde{D}^{(j-1)}_{I_{j-1}})$$

$$= I(\tilde{D}^{(j-1)}_{I_{j-1}} ; M_j) + \sum_{m_j \in (\mathcal{M}_j^c \cup \mathcal{M}_j^c)} \mu_j(m_j)H(D^{(j)}_{I_{j-1}}[m_j]) \quad \text{Defn. of } I(\cdot, \cdot).$$

$$\leq H(M_j) + \sum_{m_j \in (\mathcal{M}_j^c \cup \mathcal{M}_j^c)} \mu_j(m_j)H(D^{(j)}_{I_{j-1}}[m_j]) \quad I(X ; \cdot) \leq H(X).$$

$$\leq l_j + \sum_{m_j \in \mathcal{M}_j^c} \mu_j(m_j)H(D^{(j)}_{I_{j-1}}[m_j]) + \sum_{m_j \in \mathcal{M}_j} \mu_j(m_j)H(D^{(j)}_{I_{j-1}}[m_j]) \quad H(M_j) \leq |M_j| = l_j.$$ 

$$\leq l_j + (1 - \alpha)cE|I_{j-1}| + \alpha \left( cE - 2 \sum_{u=1}^{j} \frac{16^{j-u+1}l_u}{k^{l-1-(u-1)/r}} - 2 \cdot 22^{j-1} \right) |I_{j-1}| \quad \text{Defn. of } \mathcal{M}_j^c.$$ 

$$= l_j + \left( cE - 2\alpha \sum_{u=1}^{j} \frac{16^{j-u+1}l_u}{k^{l-1-(u-1)/r}} - 2\alpha \cdot 22^{j-1} \right) |I_{j-1}|.$$
Lemma 3.5. Fix on. These two constraints are captured by parts (2) and (1), respectively, of Lemma 3.5. We first prove that for each message $m_j$ from Lemma 3.4, having $J$ many low probability points w.r.t. $D^{(j-1)}$, since this may stop us from applying Lemma 3.2 later on. These two constraints are captured by parts (2) and (1), respectively, of Lemma 3.5.

Lemma 3.5. Fix $j \in [1,r]$ and suppose Invariant 3.3 holds for $j - 1$. Then there exists a subset of messages $M_j \subseteq M'_j$ (from Lemma 3.4) with $\mu_j(M_j) \geq 1/4$ such that for each message $m_j \in M_j$, there exists a subset $I_j \subseteq I_{j-1}$ of size $|I_j| = k^{1-j/r}$ satisfying both of the following properties:

1. $\Pr_{x_j \sim D^{(j)}_j}(x_j) < (4t)^{-|I_j|/32} \leq 1/2$;
2. Each nonempty subset $I' \subseteq I_j$ satisfies

$$H(D^{(j)}_{I'}) \geq \left(cE - 4 \sum_{u=1}^{j} \frac{16^{j-u}l_u}{k^{1-(u-1)/r}} - 4 \cdot 22^{j-1}\right) |I'|.$$ 

Proof. We first prove that for each message $m_j \in M'_j$ (from Lemma 3.4), there exists a subset $J_0 \subseteq I_{j-1}$ of size $|J_0| \geq |I_{j-1}|/2$ such that each nonempty subset $I' \subseteq J_0$ satisfies part (2) of the lemma. Suppose $J_1, J_2, \ldots, J_w$ are disjoint subsets of $I_{j-1}$, each of which violates the inequality of part (2), whereas none of the subsets of $J_0 = I_{j-1} \setminus \bigcup_{v=1}^{w} J_v$ do. Then we can upper bound the entropy of $D^{(j)}_{I_{j-1}}$ as follows.

$$H(D^{(j)}_{I_{j-1}}) \leq \sum_{v=0}^{w} H(D^{(j)}_{J_v})$$

Fact 2.1

$$< cE|J_0| + \sum_{v=1}^{w} \left(cE - 4 \sum_{u=1}^{j} \frac{16^{j-u}l_u}{k^{1-(u-1)/r}} - 4 \cdot 22^{j-1}\right) |J_v| \quad \text{Defn. of } J_v.$$

$$= cE|I_{j-1}| - 4|I_{j-1} \setminus J_0| \left(\sum_{u=1}^{j} \frac{16^{j-u}l_u}{k^{1-(u-1)/r}} + 22^{j-1}\right).$$

On the other hand, from Lemma 3.4 having $m_j \in M'_j$ guarantees that

$$H(D^{(j)}_{I_{j-1}}) \geq \left(cE - 2 \sum_{u=1}^{j} \frac{16^{j-u}l_u}{k^{1-(u-1)/r}} - 2 \cdot 22^{j-1}\right) |I_{j-1}|.$$ 

The two inequalities above are only consistent if $|I_{j-1} \setminus J_0| \leq |I_{j-1}|/2$, or equivalently $|J_0| \geq |I_{j-1}|/2$. Thus, $J_0$ exists with the right cardinality, as claimed.

Now suppose, for the purpose of obtaining a contradiction, that the lemma is false. For every $m_j \in M'_j$ there is a corresponding index set $J_0$ whose subsets satisfy part (2) of the lemma. If
the lemma is false, that means there is a subset $\mathcal{M}''_j \subseteq \mathcal{M}'_j$ of “bad” messages with $\mu_j(\mathcal{M}''_j) > 1/4$ such that, for each $m_j \in \mathcal{M}''_j$, none of the $\binom{|J_0|}{|I_j|}$ choices for $I_j \subseteq J_0$ satisfy part (1) of the lemma. (Remember that $J_0$ depends on $m_j$ but the lower bound on $|J_0| \geq |I_{j-1}|/2$ is independent of $m_j$.) Consider the following summation:

$$Z = \sum_{I_j \subseteq I_{j-1} : |I_j| = k^{1-j/r}} \sum_{x_{I_j} \in [t]^{|I_j|}} D_{I_j}^{(j-1)}(x_{I_j}).$$

We can easily upper bound $Z$ as follows.

$$Z < \left(\frac{|I_j-1|}{|I_j|}\right) \cdot 4|I_j| \cdot \frac{(4t)^{-|I_j|}}{32} = \left(\frac{|I_j-1|}{|I_j|}\right) 2^{-2|I_j|-5}.$$

Invariant 3.3(2) relates $D^{(j-1)}$ and $\widehat{D}^{(j-1)}$, which lets us lower bound $Z$.

$$Z \geq \frac{1}{4} \sum_{I_j \subseteq I_{j-1} : |I_j| = k^{1-j/r}} \sum_{x_{I_j} \in [t]^{|I_j|}} \widehat{D}_{I_j}^{(j-1)}(x_{I_j}) \quad \text{Invariant 3.3(2).}$$

By definition, $\widehat{D}^{(j-1)}$ is a convex combination of the $D^{(j)}[m_j]$ distributions, weighted according to $\mu_j(\cdot)$. Hence, the expression above is lower bounded by

$$\geq \frac{1}{4} \sum_{m_j \in \mathcal{M}''_j} \sum_{I_j \subseteq I_{j-1} : |I_j| = k^{1-j/r}} \sum_{x_{I_j} \in [t]^{|I_j|}} \mu_j(m_j) \cdot D_{I_j}^{(j)}[m_j](x_{I_j})$$

$$\geq \frac{1}{4} \sum_{m_j \in \mathcal{M}''_j} \sum_{I_j \subseteq I_{j-1} : |I_j| = k^{1-j/r}} \sum_{x_{I_j} \in [t]^{|I_j|}} \mu_j(m_j) \cdot D_{I_j}^{(j)}[m_j](x_{I_j}) \quad \text{Rearrange sums.}$$

By definition, for every $m_j \in \mathcal{M}''_j$ and every choice of $I_j \subseteq J_0$, part (1) of the lemma is violated. Continuing with the inequalities,

$$> \frac{1}{4} \sum_{m_j \in \mathcal{M}''_j} \mu_j(m_j) \cdot \left(\frac{|J_0|}{|I_j|}\right) \cdot \frac{1}{2}$$

$$> \frac{1}{32} \left(\frac{|I_j-1|/2}{|I_j|}\right).$$

Because $\mu_j(\mathcal{M}''_j) > 1/4$.

This contradicts the upper bound on $Z$ whenever $k^{1/r}$ is at least some sufficiently large constant. \qed

The receiver of $m_j$ constructs a new distribution $\widehat{D}^{(j)}$ in two steps. After fixing $I_j$, we construct $\widehat{D}^{(j)}$ by combining $D^{(j-1)}$ and $D^{(j)}$, filtering out some points in the space whose probability mass is
too low. We then construct $\tilde{D}(j)$ from $\tilde{D}(j)$ and $D^{(j-1)}$ by filtering out points that occur under $\tilde{D}(j)$ with substantially larger probability than they do under $D^{(j-1)}$.

Formally, suppose Invariant 3.3 holds for $j - 1$. For each message $m_j \in M_j$ (from Lemma 3.5), let $I_j$ be selected to satisfy both properties of Lemma 3.5. Define the probability mass of a vector $x \in [t]^k$ under $\tilde{D}(j)$ as follows:

$$
\tilde{D}(j)(x) = \begin{cases} 
0, & \text{if } D^{(j-1)}(x_{I_j}) < \frac{(4t)^{-|I_j|}}{32}; \\
\frac{D^{(j)}(x_{I_j})}{\beta_1} \cdot \frac{D^{(j-1)}(x)}{D^{(j-1)}(x_{I_j})}, & \text{otherwise.}
\end{cases}
$$

where $\beta_1$ is

$$
\beta_1 = \Pr_{x_{I_j} \sim D^{(j)}_{I_j}} \left[ D^{(j-1)}(x_{I_j}) \geq \frac{(4t)^{-|I_j|}}{32} \right].
$$

In other words, we discard a $1 - \beta_1$ fraction of the distribution $D^{(j)}$, but ignoring this effect, the projection of $\tilde{D}(j)$ onto $I_j$ has the same distribution as $D^{(j)}$ onto $I_j$, and conditioned on the value of $x_{I_j}$, the distribution $\tilde{D}(j)$ (projected onto $[k] \setminus I_j$) is identical to $D^{(j-1)}$. We derive $\hat{D}(j)$ from $\tilde{D}(j)$ with a similar transformation.

$$
\hat{D}(j)(x) = \begin{cases} 
0, & \text{if } \frac{\tilde{D}(j)(x_{I_j})}{D^{(j-1)}(x_{I_j})} > 2\gamma_j; \\
\frac{\tilde{D}(j)(x_{I_j})}{\beta_2} \cdot \frac{D^{(j-1)}(x)}{D^{(j-1)}(x_{I_j})}, & \text{otherwise.}
\end{cases}
$$

where $\beta_2$ and $\gamma_j$ are defined to be

$$
\beta_2 = \Pr_{x_{I_j} \sim \tilde{D}^{(j)}_{I_j}} \left[ \frac{\tilde{D}(j)(x_{I_j})}{\tilde{D}^{(j-1)}(x_{I_j})} \leq 2\gamma_j \right],
$$

$$
\gamma_j = \sum_{u=1}^{j} \ell_u \left( \frac{16}{k^{1/r}} \right)^{j-u+1} + (16 \cdot 22^{j-1} + 6)|I_j| + 6
$$

$$
\leq \sum_{u=1}^{j} \ell_u \left( \frac{16}{k^{1/r}} \right)^{j-u+1} + 22^j |I_j| + 6.
$$

The proofs of Lemmas 3.6 and 3.7 use several simple observations about $\tilde{D}(j)$ and $\hat{D}(j)$:

1. Lemma 3.5(1) states that $\beta_1 \geq 1/2$. Lemma 3.5(2) lower bounds the entropy of $D^{(j)}_{I_j}$. We apply Lemma 3.1 to $D^{(j)}_{I_j}$ and $\tilde{D}^{(j)}_{I_j}$ (taking the roles of $p$ and $q$, respectively) with parameter $\alpha = 1/2 \leq \beta_1$, and obtain the following lower bound on the entropy of $\tilde{D}^{(j)}_{I_j}$:

$$
H(\tilde{D}^{(j)}_{I_j}) \geq \left( cE - 8 \sum_{u=1}^{j} \frac{16^{j-u} \ell_u}{k^{1-(u-1)/r}} - 8 \cdot 22^{j-1} - 2 \right) |I_j|.
$$
2. We can then apply Lemma 3.2 to $\mathcal{D}_{I_j}^{(j-1)}$ and $\tilde{\mathcal{D}}_{I_j}^{(j)}$ (taking the roles of $p$ and $q$, respectively) with parameters

$$g_1 = 8 \sum_{u=1}^{j} \frac{16^{j-u}l_u}{k^{(j-u+1)/r}} + (8 \cdot 22^{j-1} + 2)|I_j|,$$

$$g_2 = 2|I_j| + 5,$$

and $\alpha = 1/2$.

Since $g_1/\alpha + g_2 - (1 - \alpha)\log(1 - \alpha)/\alpha = \gamma_j$, we conclude that $\beta_2 \geq 1 - \alpha = 1/2$. Thus, for each value $x_{I_j} \in \text{supp}(\tilde{\mathcal{D}}_{I_j}^{(j)})$,

$$\tilde{\mathcal{D}}_{I_j}^{(j)}(x_{I_j}) = \frac{\tilde{\mathcal{D}}_{I_j}^{(j)}(x_{I_j})}{\beta_2} = \frac{\mathcal{D}_{I_j}^{(j)}(x_{I_j})}{\beta_1\beta_2} \leq 4\mathcal{D}_{I_j}^{(j)}(x_{I_j}). \quad (2)$$

Lemma 3.6 completes the inductive step by lower bounding the entropy of $\tilde{\mathcal{D}}_{I_j}^{(j)}$ for every nonempty subset $I' \subseteq I_j$. To put it another way, it ensures that the coordinates in $I_j$ remain almost completely unknown to both parties.

**Lemma 3.6.** Fix $j \in [1, r]$ and suppose Invariant 3.3 holds for $j - 1$. Then, for each message $m_j \in \mathcal{M}_j$ (from Lemma 3.5), Invariant 3.3 also holds for $j$.

**Proof.** Due to Lemma 3.5 and Eqn. (2), the first two properties of Invariant 3.3 are satisfied. For each nonempty subset $I' \subseteq I_j$, the third property of Invariant 3.3 can be derived from the second property of Lemma 3.5 and an application of Lemma 3.1 to $\mathcal{D}_{I'}^{(j)}$ and $\tilde{\mathcal{D}}_{I'}^{(j)}$ (taking the roles of $p$ and $q$, respectively) with parameter $\alpha = 1/4$ as follows.

$$H(\tilde{\mathcal{D}}_{I'}^{(j)}) \geq \left(cE - 16 \sum_{u=1}^{j} \frac{16^{j-u}l_u}{k^{(j-u-1)/r}} - 16 \cdot 22^{j-1} - 4 \right)|I'| \geq \left(cE - \sum_{u=1}^{j} \frac{16^{j-u+1}l_u}{k^{(j-u-1)/r}} - 22^{j} \right)|I'|.$$

□

Aside from maintaining Invariant 3.3 round by round, another important part of our proof is to compute the error probability. Lemma 3.7 shows how the error probabilities of two consecutive rounds are related after our modification to the protocol. More importantly, it also illustrates the reason to bound the pointwise ratio between $\tilde{\mathcal{D}}_{I_j}^{(j)}$ and $\mathcal{D}_{I_j}^{(j-1)}$.

**Lemma 3.7.** Fix a round $j \in [1, r]$ and suppose Invariant 3.3 holds for $j - 1$. Fix any specific message $m_j \in \mathcal{M}_j$ (from Lemma 3.5). Define $p$ to be the probability of error, when the protocol begins after round $j$ with the inputs drawn from $\mathcal{D}^{(j)}$ and $\tilde{\mathcal{D}}^{(j)}$, respectively. Then the probability of error is at least $2^{-\gamma_j - 1}p$ when the inputs are instead drawn from $\mathcal{D}^{(j)}$ and $\mathcal{D}^{(j-1)}$, respectively.

**Proof.** From the definition of $\tilde{\mathcal{D}}^{(j)}$, for each value $x \in \text{supp}(\tilde{\mathcal{D}}^{(j)})$, we have

$$\frac{\tilde{\mathcal{D}}^{(j)}(x)}{\mathcal{D}^{(j-1)}(x)} = \frac{\tilde{\mathcal{D}}^{(j)}(x_{I_j})}{\beta_2\mathcal{D}^{(j-1)}(x_{I_j})} \leq 2^{\gamma_j} \beta_2 \leq 2^{\gamma_j + 1}. \quad (3)$$

This essentially concludes the proof. □
Finally, with all lemmas proved above, we have reached the point to calculate the initial error probability.

**Lemma 3.8.** Recall that $c = 1/2, c' = c/100$. Fix any $r \in [1, (\log k)/6]$ and $E \geq 100k^{1-1/r}/c$. Suppose the initial input vectors are drawn independently and uniformly from $[t]^k$, where $t = 2^{cE}$. Then the error probability of the *EqualityTesting* protocol, $p_{err}$, is greater than $2^{-E}$.

**Proof.** First suppose Invariant 3.3 holds for $r$ and consider the situation after the final round, where the inputs are drawn from $\tilde{D}^{(r)}$ and $\hat{D}^{(r)}$, respectively. Notice that $I_r$ is a singleton set, so the entropy of $\hat{D}^{(r)}_{I_r}$ can be lower bounded as follows.

$$H(\hat{D}^{(r)}_{I_r}) \geq cE - \sum_{u=1}^{r} \frac{16^{r-u+1}u}{k^{1-(u-1)/r}} - 22^r \quad \text{Invariant 3.3 (3)}.$$

$$= cE - \frac{16}{k^{1/r}} \sum_{u=1}^{r} l_u \left(\frac{16}{k^{1/r}}\right)^{r-u} - 22^r$$

$$\geq cE - \frac{16}{k^{1/r}} \sum_{u=1}^{r} l_u - 22k^{1-1/r}, \quad k^{1/r} \geq 2^6 \text{ due to } r \leq (\log k)/6.$$

$$\geq cE - 16c'E - 22k^{1-1/r} > \frac{cE}{2}, \quad \text{Because } \sum_{u=1}^{r} l_u \leq c'E k^{1/r}.$$

From the lower bound on the entropy of $\hat{D}^{(r)}_{I_r}$, we can easily show that there exists no value $x_{I_r}$ such that $\hat{D}^{(r)}_{I_r}(x_{I_r}) = \alpha > 3/4$. If there were such a value, then the entropy of $\hat{D}^{(r)}_{I_r}$ can also be upper bounded as

$$H(\hat{D}^{(r)}_{I_r}) \leq \alpha \log \frac{1}{\alpha} + (1-\alpha) \log \frac{t}{1-\alpha} < \frac{cE}{4} + \alpha \log \frac{1}{\alpha} + (1-\alpha) \log \frac{1}{1-\alpha} < \frac{cE}{2},$$

contradicting the lower bound on $H(\hat{D}^{(r)}_{I_r})$.

After all $r$ rounds of communication, the receiver of the last message has to make the decision on $I_r$ depending only on his own input on $I_r$. Let $x_0 \subseteq [t]$ be the subset of values $x_{I_r}$ such that the protocol outputs “not equal” on $I_r$ upon seeing the input $x_{I_r}$ after $r$ rounds of communication, $x_1 = [t] \setminus x_0$, and $\beta = \hat{D}^{(r)}_{I_r}(x_0)$. Then, the final error probability is at least

$$\sum_{x_{I_r} \in x_0} \hat{D}^{(r)}_{I_r}(x_{I_r}) \mathcal{D}^{(r)}_{I_r}(x_{I_r}) + \sum_{x_{I_r} \in x_1} \hat{D}^{(r)}_{I_r}(x_{I_r}) \left(1 - \mathcal{D}^{(r)}_{I_r}(x_{I_r})\right)$$

$$= \sum_{x_{I_r} \in x_0} \hat{D}^{(r)}_{I_r}(x_{I_r}) \mathcal{D}^{(r)}_{I_r}(x_{I_r}) + \sum_{x_{I_r} \in x_1} \hat{D}^{(r)}_{I_r}(x_{I_r}) \sum_{x'_{I_r} \neq x_{I_r}} \mathcal{D}^{(r)}_{I_r}(x'_{I_r})$$

$$\geq \frac{1}{4} \sum_{x_{I_r} \in x_0} \hat{D}^{(r)}_{I_r}(x_{I_r})^2 + \frac{1}{4} \sum_{x_{I_r} \in x_1} \hat{D}^{(r)}_{I_r}(x_{I_r}) \sum_{x'_{I_r} \neq x_{I_r}} \hat{D}^{(r)}_{I_r}(x'_{I_r}) \quad \text{Invariant 3.3 (2)}. \quad$$

$$= \frac{1}{4} \sum_{x_{I_r} \in x_0} \hat{D}^{(r)}_{I_r}(x_{I_r})^2 + \frac{1}{4} \sum_{x_{I_r} \in x_1} \hat{D}^{(r)}_{I_r}(x_{I_r}) \left(1 - \hat{D}^{(r)}_{I_r}(x_{I_r})\right)$$

$$\geq \frac{1}{4} \sum_{x_{I_r} \in x_0} \hat{D}^{(r)}_{I_r}(x_{I_r})^2 + \frac{1}{16} \sum_{x_{I_r} \in x_1} \hat{D}^{(r)}_{I_r}(x_{I_r}) \quad \text{Because } \hat{D}^{(r)}_{I_r}(x_{I_r}) \leq 3/4.$$

16
\[ \frac{\beta^2}{4t} + \frac{1 - \beta}{16} \geq \frac{1}{4t}. \]

Convexity of \( x^2 \).

This result also meets the simple intuition that when the inputs to the two parties are almost uniformly random and no communication is allowed, the best strategy would be guessing “not equal” regardless of the actual input.

Finally, we are ready to transfer the error probability back round by round. From Lemma 3.5 through Lemma 3.7, the error probability w.r.t. \( D(j) \) and \( \hat{D}(j) \) differs from the error probability w.r.t. \( D(j-1) \) and \( \hat{D}(j-1) \) by at most a \( 4 \cdot 2^{\gamma_j + 1} = 2^{\gamma_j + 3} \) factor. In particular, Lemma 3.5 and Lemma 3.6 say that the \( j \)th message \( m_j \) satisfies Invariant 3.3 at index \( j \) with probability at least \( \frac{1}{4} \), provided Invariant 3.3 holds for \( j-1 \), and Lemma 3.7 says the error probabilities under the two measures differ by a \( 2^{\gamma_j + 1} \) factor for any such \( m_j \). Repeating this for each \( j \in [1, r] \), we conclude that the initial error probability \( p_{err} \) is lower bounded by

\[
p_{err} \geq \frac{1}{4t} \cdot \exp \left( -3r - \sum_{j=1}^{r} \gamma_j \right) = \exp \left( -cE - 2 - 3r - \sum_{j=1}^{r} \gamma_j \right) > 2^{-E},
\]

since

\[
\begin{aligned}
&cE + 2 + 3r + \sum_{j=1}^{r} \gamma_j \\
&\leq cE + 2 + 3r + 6r + \sum_{j=1}^{r} \sum_{u=1}^{r} \frac{16}{k^{1/r}} \left( \frac{16}{k^{1/r}} \right)^{j-u} + \sum_{j=1}^{r} 22j |I_j| \\
&\leq cE + 11r + \sum_{u=1}^{r} \frac{16l_u}{k^{1/r}} \sum_{j=1}^{r} \frac{16}{k^{1/r}} \left( \frac{16}{k^{1/r}} \right)^{j-u} + 22k^{1-1/r} \sum_{j=1}^{r} \left( \frac{22}{k^{1/r}} \right)^{j-1} \\
&\leq cE + 11r + \frac{32}{k^{1/r}} \sum_{u=1}^{r} l_u + 44k^{1-1/r} \\
&\leq cE + \frac{11cE}{100} + \frac{32cE}{100} + \frac{44cE}{100} < E.
\end{aligned}
\]

Because \( \sum_{u=1}^{r} l_u \leq c'E^{k^{1/r}} \).

Proof of Theorem 2. Lemma 3.8 actually shows that given integers \( k \geq 1 \) and \( r \leq (\log k)/6 \), any \( r \)-round deterministic protocol for EqualityTesting on vectors of length \( k \) that has distributional error probability \( p_{err} = 2^{-E} \) with respect to the uniform input distribution on \( [t]^k \), where \( t = 2^cE \), requires at least \( \Omega(E k^{1/r}) \) bits of communication. Notice that the additional assumption \( E \geq 100k^{1-1/r}/c \) always makes sense since there is a trivial \( \Omega(k) \) lower bound on the communication complexity of EqualityTesting, regardless of \( r \). Thus, Theorem 2 follows directly from Yao’s minimax principle. □

### 3.3 A Lower Bound on ExistsEqual

The proof of Theorem 3 is almost the same as that of Theorem 2 except for the final step, namely Lemma 3.8 in which we first compute the final error probability after all \( r \) rounds of communication and then transfer it backward round by round using Lemma 3.7. The problem with applying the
same argument to ExistsEqual protocols is that the receiver of the last message may be able to announce the correct answer, even though it knows little information about the inputs on the single coordinate $I_r$.

In order to prove Theorem 3.8, first notice that Lemma 3.4 through Lemma 3.7 also hold perfectly well for ExistsEqual protocols as no modification is required in their proofs. Therefore, it is sufficient to prove the following Lemma 3.9 which is an analog of Lemma 3.8 for ExistsEqual. It is based mainly on Markov’s inequality.

**Lemma 3.9.** Recall that $c = 1/2, c' = c/100$. Consider an execution of a deterministic $r$-round ExistsEqual protocol, $r \in [1, (\log k)/6]$, on input vectors drawn independently and uniformly from $[t]^k$, where $t = 2^c$. Here $E \geq 100k^{1-1/c}$ if $r > 1$ and $E \geq (100 \log k)/c$ otherwise. Then the protocol errs with probability $p_{\text{err}} > 2^{-E}$.

**Proof.** Similarly to the proof of Lemma 3.8, we first consider the situation after the final round. In the ExistsEqual protocol, the receiver of the last message can make the decision depending on every coordinate of his own input. Let $\mathcal{X}_0 \subseteq [t]^k$ be the subset of values $x$ such that the protocol outputs “no” upon seeing the input $x$ after $r$ rounds of communication, $\mathcal{X}_1 = [t]^k \setminus \mathcal{X}_0$. Then, the final error probability is at least

$$
\sum_{x \in \mathcal{X}_0} \hat{D}^{(r)}(x) \mathcal{D}^{(r)}(x_i) + \sum_{x \in \mathcal{X}_1} \hat{D}^{(r)}(x) \left(1 - \sum_{y \in \mathcal{N}(x)} \mathcal{D}^{(r)}(y)\right),
$$

where $\mathcal{N}(x) = \{y \in [t]^k \mid$ there exists some $i \in [k]$ such that $x_i = y_i\}$ is the subset of input vectors that agree with $x$ on at least one coordinate.

The main difficulty here is to lower bound $1 - \sum_{y \in \mathcal{N}(x)} \mathcal{D}^{(r)}(y)$, which is potentially quite small. Consider the following summation $Z_0$ over all transcripts $m_1, \ldots, m_r$ in which $m_j \in \mathcal{M}_j$ (from Lemma 3.5), where the set $\mathcal{M}_j$ depends on $m_1, \ldots, m_{j-1}$:

$$Z_0 = \sum_{m_1 \in \mathcal{M}_1} \mu_1(m_1) \sum_{m_2 \in \mathcal{M}_2} \mu_2(m_2) \cdots \sum_{m_r \in \mathcal{M}_r} \mu_r(m_r) \sum_{x \in [t]^k} \hat{D}^{(r)}(x) \sum_{y \in \mathcal{N}(x)} \mathcal{D}^{(r)}(y).$$

From the proof of Lemma 3.7 (Eqn. (3)), we can upper bound $Z_0$ as follows.

$$Z_0 \leq \sum_{m_1 \in \mathcal{M}_1} \mu_1(m_1) \cdots \sum_{m_r \in \mathcal{M}_r} \mu_r(m_r) \sum_{x \in [t]^k, y \in \mathcal{N}(x)} 2^{r+1} \cdot \mathcal{D}^{(r-1)}(x) \cdot \mathcal{D}^{(r)}(y).$$

Notice that $\gamma_r$ and $\mathcal{D}^{(r-1)}$ are independent of the choice of $m_r$, hence by rearranging sums, this is equal to

$$= \sum_{m_1 \in \mathcal{M}_1} \mu_1(m_1) \cdots \sum_{m_{r-1} \in \mathcal{M}_{r-1}} \mu_{r-1}(m_{r-1}) \sum_{x \in [t]^k, y \in \mathcal{N}(x)} 2^{r+1} \cdot \mathcal{D}^{(r-1)}(x) \sum_{m_r \in \mathcal{M}_r} \mu_r(m_r) \cdot \mathcal{D}^{(r)}(y).$$

By definition, $\hat{D}^{(r-1)}$ is a convex combination of the $\mathcal{D}^{(r)}[m_r]$ distributions, weighted according to $\mu_r(\cdot)$. Hence, the expression above is upper bounded by

$$\leq \sum_{m_1 \in \mathcal{M}_1} \mu_1(m_1) \cdots \sum_{m_{r-1} \in \mathcal{M}_{r-1}} \mu_{r-1}(m_{r-1}) \sum_{x \in [t]^k, y \in \mathcal{N}(x)} 2^{r+1} \cdot \mathcal{D}^{(r-1)}(x) \cdot \hat{D}^{(r-1)}(y)$$
By the symmetry of $x$ and $y$, this is equal to

$$= \sum_{m_1 \in \mathcal{M}_1} \mu_1(m_1) \cdots \sum_{m_r \in \mathcal{M}_r} \mu_r(m_r-1) \sum_{x \in [t]^k, y \in \mathcal{N}(x)} 2^{2^r+1} \cdot \hat{D}^{(r-1)}(x) \cdot D^{(r-1)}(y)$$

We repeat the same argument for rounds $r - 1$ down to 1, upper bounding $Z_0$ by

$$\leq \exp \left( r + \sum_{j=1}^r \gamma_j \right) \cdot \sum_{x \in [t]^k, y \in \mathcal{N}(x)} \hat{D}^{(0)}(x) \cdot D^{(0)}(y)$$

$$\leq \exp \left( r + \sum_{j=1}^r \gamma_j \right) \cdot \frac{k}{t}$$

The last inequality above follows from a union bound since, under the initial distributions $\hat{D}^{(0)}, D^{(0)}$, each of the $k$ coordinates is equal with probability $1/t$. Recall that $E \geq 100k^{1-1/r}/c$ when $r > 1$ and $E \geq (100 \log k)/c$ otherwise. Hence, using the same argument as that in the proof of Lemma 3.8, we can further bound this as

$$\leq 2^{0.83cE} \cdot 2^{0.02cE} \cdot 2^{-cE} = 2^{-0.15cE},$$

since

$$r + \sum_{j=1}^r \gamma_j \leq 7r + \sum_{j=1}^r \sum_{u=1}^j l_u \left( \frac{16}{k^{1/r}} \right)^{j-u+1} + \sum_{j=1}^r 22^j |I_j| \leq \frac{7cE}{100} + \frac{32cE}{100} + \frac{44cE}{100} = \frac{83cE}{100},$$

and $k \leq (cE/100)^{r/(r-1)} \leq (cE/100)^2 \leq 2^{0.02cE}$ when $r > 1$ and $k \leq 2^{0.01cE}$ otherwise.

Now fix a round $j$ and a particular history $(m_1, ..., m_j)$ up to round $j$ such that $m_{j'} \in \mathcal{M}_{j'}$ holds for every $j' \geq j$. Define $Z_j$ as follows.

$$Z_j = \sum_{m_{j+1} \in \mathcal{M}_{j+1}} \mu_{j+1}(m_{j+1}) \cdots \sum_{m_r \in \mathcal{M}_r} \mu_r(m_r) \sum_{x \in [t]^k} \hat{D}^{(r)}(x) \sum_{y \in \mathcal{N}(x)} D^{(r)}(y).$$

By Markov’s inequality, there exists a subset of messages $\hat{M}_1 \subseteq \mathcal{M}_1$ with $\mu_1(\hat{M}_1) \geq \mu_1(\mathcal{M}_1)/2 \geq 1/8$ such that each message $m_1 \in \hat{M}_1$ satisfies $Z_1 \leq 2Z_0/\mu_1(\mathcal{M}_1) \leq 8Z_0$ since $\mu_1(\mathcal{M}_1) \geq 1/4$ from Lemma 3.3. Similarly, conditioned on any specific $m_1 \in \mathcal{M}_1$, by Markov’s inequality, there exists a subset of messages $\hat{M}_2 \subseteq \mathcal{M}_2$ with $\mu_2(\hat{M}_2) \geq \mu_2(\mathcal{M}_2)/2 \geq 1/8$ such that each message $m_2 \in \hat{M}_2$ satisfies $Z_2 \leq 2Z_1/\mu_2(\mathcal{M}_2) \leq 8^2Z_0$. In general, conditioned on any specific partial transcript $m_1, ..., m_{j-1}$ such that $m_{j'} \in \mathcal{M}_{j'}$ holds for every $j' < j$, there exists a subset of messages $\hat{M}_j \subseteq \mathcal{M}_j$ with $\mu_j(\hat{M}_j) \geq \mu_j(\mathcal{M}_j)/2 \geq 1/8$ such that each message $m_j \in \hat{M}_j$ satisfies $Z_j \leq 8^jZ_j$.

After repeating the same argument $r$ times, we get $\hat{M}_1, ..., \hat{M}_r$ in sequence. For any sampled transcript $m_1, ..., m_r$ such that $m_j \in \hat{M}_j$ for all $j \leq r$, we have

$$Z_r \leq 8^rZ_0 \leq 2^{3r} \cdot 2^{-0.15cE} \leq 2^{-0.12cE} \leq \frac{1}{4},$$

19
as $r \leq cE/100$ and $cE \geq 100$. Further, one more application of Markov’s inequality shows that there exists a subset of values $\mathcal{X}' \subseteq [t]^k$ with $\hat{D}^{(r)}(\mathcal{X}') = \alpha \geq 1/2$ such that $\sum_{y \in \mathcal{N}(x)} D^{(r)}(y) \leq 1/2$ holds for every $x \in \mathcal{X}'$.

As a result, we can then lower bound the final error probability as follows, where $\beta = \hat{D}^{(r)}(\mathcal{X}_0 \cap \mathcal{X}')$.

$$
\sum_{x \in \mathcal{X}_0} \hat{D}^{(r)}(x) D^{(r)}_I(x_{I_r}) + \sum_{x \in \mathcal{X}_1} \hat{D}^{(r)}(x) \left(1 - \sum_{y \in \mathcal{N}(x)} D^{(r)}(y)\right)
\geq \sum_{x \in (\mathcal{X}_0 \cap \mathcal{X}')} \hat{D}^{(r)}(x) D^{(r)}_I(x_{I_r}) + \sum_{x \in (\mathcal{X}_1 \cap \mathcal{X}')} \hat{D}^{(r)}(x) \left(1 - \sum_{y \in \mathcal{N}(x)} D^{(r)}(y)\right)
\geq \frac{1}{4} \sum_{x \in (\mathcal{X}_0 \cap \mathcal{X}')} \hat{D}^{(r)}(x) \hat{D}^{(r)}_I(x_{I_r}) + \sum_{x \in (\mathcal{X}_1 \cap \mathcal{X}')} \hat{D}^{(r)}(x) \left(1 - \sum_{y \in \mathcal{N}(x)} D^{(r)}(y)\right)
\geq \frac{1}{4} \sum_{x \in (\mathcal{X}_0 \cap \mathcal{X}') \cap \mathcal{X}'} \hat{D}^{(r)}(x) \hat{D}^{(r)}_I(x_{I_r}) + \frac{1}{2} \sum_{x \in (\mathcal{X}_1 \cap \mathcal{X}')} \hat{D}^{(r)}(x)
$$

Defn. of $\mathcal{X}'$.

In order to minimize the above expression, we can now assume without loss of generality that the partition between $\mathcal{X}_0 \cap \mathcal{X}'$ and $\mathcal{X}_1 \cap \mathcal{X}'$ depends solely on $x_{I_r}$ as only the relative magnitude of $\hat{D}^{(r)}_I(x_{I_r})/4$ and $1/2$ matters. Continuing,

$$
\geq \frac{\beta^2}{4t} + \alpha - \frac{\alpha^2}{4t} \geq \frac{1}{16t}.
$$

Convexity of $x^2$.

Finally, we are ready to transfer the error probability back in exactly the same manner as we did in the proof of Lemma 3.8. Using a similar argument, the existence of $\hat{M}_j$ guarantees that

$$
p_{err} \geq \frac{1}{16t} \cdot \exp\left(-4r - \sum_{j=1}^{r} \gamma_j\right) = \exp\left(-cE - 4r - \sum_{j=1}^{r} \gamma_j\right) > 2^{-E},
$$

since

$$
cE + 4 + 4r + \sum_{j=1}^{r} \gamma_j \leq cE + \frac{14cE}{100} + \frac{32cE}{100} + \frac{44cE}{100} < E.
$$

\[ \square \]

**Proof of Theorem** 4.4 Similarly to the proof of Theorem 2.2 Theorem 4 follows from Lemma 3.9 and a direct application of Yao’s minimax principle. \[ \square \]

### 4 Upper Bounds on EqualityTesting and ExistsEqual

In this section, we prove upper bounds on both EqualityTesting and ExistsEqual. We first give a $(\log^*(k/E) + r)$-round EqualityTesting protocol (Theorem 4.1) that uses $O(k + rEk^{1/r})$ bits of communication and errs with probability at most $p_{err} = 2^{-E}$. The log*(k/E) term cannot be
completely eliminated, due to the lower bounds of \cite{ST13, BCK16}. Our lower bound implies that when \( E \geq k \) (so \( \log^*(k/E) = 0 \)), the second term is optimal up to a factor of \( r \).

A natural goal is to achieve optimal communication \( \Theta(k + E) \) and minimize the number of rounds subject to that constraint. When \( E \geq k \) our lower bound says \( r = \Omega(\log k) \), but in this case the algorithm of Theorem 4 only achieves \( O(E \log k) \) communication. Theorems 5 and 6 illustrate two ways to shave off this factor of \( r \). Theorem 5 applies to the easier \textbf{ExistsEqual} problem, and Theorem 6 applies to the general \textbf{EqualityTesting} problem, but blows up the round complexity to \( \log^*(k/E) + O(r) \).

**Theorem 4.** There exists a \((\log^*(k/E) + r)\)-round randomized protocol for \textbf{EqualityTesting} on vectors of length \( k \) that errs with probability \( p_{\text{err}} = 2^{-E} \), using \( O(k + rEk^{1/r}) \) bits of communication.

**Theorem 5.** There exists a \((\log^*(k/E) + r)\)-round randomized protocol for \textbf{ExistsEqual} on vectors of length \( k \) that errs with probability \( p_{\text{err}} = 2^{-E} \), using \( O(k + Ek^{1/r}) \) bits of communication.

**Theorem 6.** There exists a \((\log^*(k/E) + O(r))\)-round randomized protocol for \textbf{EqualityTesting} on vectors of length \( k \) that errs with probability \( p_{\text{err}} = 2^{-E} \), using \( O(k + Ek^{1/r}) \) bits of communication.

**Remark 1.** The \( \log^*(k/E) \) terms in the round complexity of Theorems 4–6 are not absolute. They can each be replaced with \( \max\{0, \log^*(k/E) - \log^*(C)\} \), at the cost of increasing the communication by \( O(Ck) \).

### 4.1 Overview and Preliminaries

We start by giving a generic protocol for \textbf{EqualityTesting}. The protocol uses a simple subroutine for \textbf{ExistsEqual}/\textbf{EqualityTesting} when \( k = 1 \). Suppose Alice and Bob hold \( x, y \in U = \{0, 1\}^l \), respectively. Alice picks a random \( w \in \{0, 1\}^l \) from the shared random source and sends Bob \( \hat{x} = \langle x, w \rangle \mod 2 \), where \( \langle \cdot, \cdot \rangle \) is the inner product operator. Bob computes \( \hat{y} = \langle y, w \rangle \mod 2 \) and declares \( \langle x, y \rangle \mod 2 = \hat{x} = \hat{y} \). Clearly, Bob never errs if \( x = y \); it is straightforward to show that the probability of error is exactly 1/2 when \( x \neq y \). We call this protocol an \emph{inner product test} and \( \hat{x}, \hat{y} \) test bits. A \( b \)-bit \emph{inner product test} on \( x \) and \( y \) refers to \( b \) independent inner product tests on \( x \) and \( y \).

The entire protocol is divided into several phases. Before phase \( j \), \( j \geq 1 \), Alice and Bob agree on a subset \( I_{j-1} \) of coordinates on which all previous inner product tests have passed. In other words, they have not yet witnessed that any of the coordinates in \( I_{j-1} \) are not equal. Each coordinate \( i \in I_{j-1} \) represents either an actual equality \( (x_i = y_i) \), or a \emph{false positive} \( (x_i \neq y_i) \). At the beginning of the protocol, \( I_0 = [k] \). In phase \( j \), we perform \( l_j \) independent inner product tests on each coordinate in \( I_{j-1} \) and let \( I_j \subseteq I_{j-1} \) be the remaining coordinates that pass all their respective inner product tests. Notice that each coordinate in \( I_{j-1} \) corresponding to equality will always pass all the tests and enter \( I_j \), while those corresponding to inequalities will only enter \( I_j \) with probability \( 2^{-b} \). At the end of the protocol, we declare all coordinates in \( I_r \) \emph{equal} and all other coordinates \emph{not equal}.

This finishes the description of our generic protocol. Theorems 4–6 all use the framework of the generic protocol and mainly differ in the details, such as how Alice and Bob exchange their test bits, how they decide \( l_j \), and when the protocol terminates.

#### 4.1.1 A protocol for exchanging test bits

For \textbf{EqualityTesting}, it is possible that a constant fraction of the coordinates are actually equalities, which makes \(|I_j| = \Theta(k)\) for every \( j \). The naive implementation explicitly exchanges all \( l_j |I_{j-1}| \) test
bits and uses $\Omega(kE)$ bits of communication in total. All the test bits corresponding to equalities are “wasted” in a sense.

For our application, it is important that the communication volume that Alice and Bob use to exchange their test bits in phase $j$ be proportional to the number of false positives in $I_{j-1}$, instead of the size of $I_{j-1}$. We will use a slightly improved version of a protocol of Feder et al. \cite{FKNN95} for exchanging the test bits.

Imagine packing the test bits into vectors $\hat{x}, \hat{y} \in B^{I_{j-1}}$ where $B = \{0, 1\}^j$. Lemma \ref{lem:packing} shows that Alice can transmit $\hat{x}$ to Bob, at a cost that depends on an \textit{a priori} upper bound on the Hamming distance $\text{dist}(\hat{x}, \hat{y})$, i.e., the number of the coordinates in $I_{j-1}$ where they differ.

**Lemma 4.1** (Cf. Feder et al. \cite{FKNN95}). Suppose Alice and Bob hold length-$K$ vectors $x, y \in B^K$, where $B = \{0, 1\}^L$. Alice can send one $O(dL + d\log(K/d))$-bit message to Bob, who generates a string $x' \in B^K$ such that the following holds. If the Hamming distance $\text{dist}(x, y) \leq d$ then $x = x'$; if $\text{dist}(x, y) > d$ then there is no guarantee.

**Proof.** Define $G = (V, E)$ to be the graph on $V = B^K$ such that $\{u, v\} \in E$ iff $\text{dist}(u, v) \leq 2d$. The maximum degree in $G$ is clearly at most $\Delta = (K_{2d}) \cdot 2^{2Ld}$ since there are $(K_{2d})$ ways to select the $2d$ indices and $2^{2Ld}$ ways to change the coordinates at those indices so that there are at most $2d$ different coordinates. Let $\phi : V \mapsto [\Delta + 1]$ be a proper $(\Delta + 1)$-coloring of $G$. Alice sends $\phi(x)$ to Bob, which requires $\log(\Delta + 1) = O(dL + d\log(K/d))$ bits. Every string in the radius-$d$ ball around $y$ (w.r.t. dist) is colored differently since they are all at distance at most $2d$, hence if $\text{dist}(x, y) \leq d$, Bob can reconstruct $x$ without error. \hfill $\square$

**Corollary 4.2.** Suppose at phase $j$, it is guaranteed that the number of false positives in $I_{j-1}$ is at most $k_{j-1}$. Then phase $j$ can be implemented with $O(k_{j-1}l_j + k_{j-1}\log(k/k_{j-1}))$ bits in 2 rounds.

Finally, a naive implementation of the protocol requires $2r$ rounds if the generic protocol has $r$ phases. In fact, the protocol can be compressed into exactly $r$ rounds in the following way. At the beginning, both parties agree that $I_0 = [k]$. Alice generates her $l_1|I_0|$ test bits $\hat{x}^{(1)}$ for phase 1 and communicates them to Bob; Bob first generates his own test bits $\hat{y}^{(1)}$ for phase 1 and determines $I_1$, then generates $l_2|I_1|$ test bits $\hat{y}^{(2)}$ for phase 2 and transmits both $\hat{y}^{(1)}$ and $\hat{y}^{(2)}$ to Alice. Alice computes $I_1$, generates $\hat{x}^{(2)}$, computes $I_2$, generates $\hat{x}^{(3)}$, and sends $\hat{x}^{(2)}$ and $\hat{x}^{(3)}$ to Bob, and so on. There is no asymptotic increase in the communication volume.

### 4.1.2 Reducing the number of false positives

Our protocols for \texttt{EqualityTesting} and \texttt{ExistsEqual} are divided into two parts. The goal of the first part is to reduce the number of false positives from at most $k$ to at most $E$; if $E \geq k$, we can skip this part. Since the number of false positives is large in this part, we can use standard Chernoff bounds to control the number of false positives surviving each phase. The details are very similar to the upper bound in Sağlam and Tardos \cite{ST13}.

**Theorem 7.** Let $(x, y)$ be an instance of \texttt{ExistsEqual} with $|x| = |y| = k$. In $\log^*(k/E)$ rounds, we can reduce this to a new instance $(x', y')$ of \texttt{ExistsEqual} where $|x'| = |y'| \leq E$, using $O(k)$ communication. The failure probability of this protocol is at most $2^{-(E+1)}$.

For \texttt{EqualityTesting}, we can reduce the initial instance to a new instance $(x', y')$ such that the Hamming distance $\text{dist}(x', y') \leq E$, with the same round complexity, communication volume, and error probability.
Proof. We first give the protocol for ExistsEqual, then apply the necessary changes to make it work for EqualityTesting.

The protocol for ExistsEqual uses our generic protocol, and imposes a strict upper bound $k_j$ on $|I_j|$. Whenever $|I_j|$ exceeds this upper bound, we halt the entire protocol and answer yes (there exists a coordinate where the input vectors are equal). We start by setting the parameters $k_j$ and $l_j$ for any $j \in [1, \log^*(k/E)]$ as follows.

\[ k_0 = k, \]
\[ k_j = \max\left\{ \frac{k}{2^{j-1}\exp(j/2)}, E \right\}, \]
\[ l_j = 3 + \exp(j-1)(2). \]

Note that it is reasonable to assume $k_j > E$ before the last phase, since whenever we find $k_j \leq E$, we can simply terminate the protocol prematurely after phase $j$, and our goal would be achieved.

Now suppose the input vectors share no equal coordinates. We know that $|I_{j-1}| \leq k_{j-1}$ at the beginning of phase $j$. The probability of any particular coordinate in $I_{j-1}$ passing all tests in phase $j$ is exactly $p_j = \exp(-l_j)$. Thus, the expected size of $I_j$ is at most

\[ k_j - 1p_j = \frac{k}{2^{j-2}\exp(j-1)(2)} \cdot \frac{1}{2^3\exp(j/2)} \leq \frac{k}{2^{j+2}\exp(j/2)} \leq \frac{k_j}{8}. \]

Recall the statement of the usual Chernoff bound.

**Fact 4.3** (See [DP09]). Let $X = \sum_{i=1}^n X_i$, where each $X_i$ is an i.i.d. Bernoulli random variable. Letting $\mu = \text{E}[X]$, the following inequality holds for any $\delta > 0$.

\[ \Pr[X \geq (1 + \delta)\mu] \leq \left( \frac{e^\delta}{(1 + \delta)^{1+\delta}} \right)^\mu. \]

In our case $X_i = 1$ iff the $i$th coordinate in $I_{j-1}$ survives to $I_j$. By linearity of expectation, $\mu \leq k_j/8$. Setting $\delta = k_j/\mu - 1 \geq 7$, we have

\[ \Pr[X \geq k_j] = \Pr[X \geq (1 + \delta)\mu] \leq \left( \frac{e^\delta}{(1 + \delta)^{1+\delta}} \right)^{k_j/8} < 0.3^{k_j} < 2^{-1.7k_j}. \]

The second to last inequality holds since $\left( \frac{e^\delta}{(1 + \delta)^{1+\delta}} \right)^{1+\delta} < 0.3$ when $\delta \geq 7$.

Hence, the probability that there are at least $k_j$ coordinates remaining after phase $j$ is at most $2^{-1.7k_j}$, and the probability this happens in any phase is at most $\sum_j 2^{-1.7k_j} \leq 2^{-(E+1)}$. Notice that when $x$ and $y$ share at least one equal coordinate, the error probability of this protocol is 0 because if it fails to reduce the number of coordinates to $E$ it (correctly) answers yes. The communication volume of the protocol is asymptotic to

\[ \sum_j l_j|I_{j-1}| \leq \sum_j l_jk_{j-1} = \sum_j O(k/2^j) = O(k). \]

For EqualityTesting, we use the same $k_j$ as an upper bound on the number of false positives in $I_j$, instead of the size of $I_j$. Since the number of false positives is at most $k$ at the beginning, we
can still use the same argument to show that with the same choice of \( k_j \) and \( l_j \), after \( \log^*(k/E) \) phases, the number of false positives is at most \( E \) with error probability \( 2^{-(E+1)} \). By Corollary 4.2, the number of bits we need to exchange in phase \( j \) is \( O(k_{j-1}l_j + k_{j-1}\log(k/k_{j-1})) \). Notice that \( \log(k/k_{j-1}) = \frac{j}{2} + \exp(j - 2)(2) = O(l_j) \), so the total communication volume is still \( O(k) \). 

In all of our protocols, we first apply Theorem 7 to reduce the number of coordinates (in the case of \( \text{ExistsEqual} \)) or false positives (in the case of \( \text{EqualityTesting} \)) to be at most \( E \). This requires no communication if \( E \geq k \) to begin with. Hence, with \( \log^*(k/E) \) extra rounds and \( O(k) \) communication, we will assume henceforth that all instances of \( \text{ExistsEqual} \) have \( E \geq k \) and instances of \( \text{EqualityTesting} \) have \( \text{dist}(x, y) \leq E \).

### 4.2 An \( O(k + rEk_0^{1/r}) \)-bit EqualityTesting Protocol

In light of Theorem 7, we can assume that the input vectors to \( \text{EqualityTesting} \) are guaranteed to differ in at most \( k_0 = \min\{k, E\} \) coordinates.

**Theorem 8.** Fix any \( k \geq 1, E \geq 1, \) and \( r \in [1, (\log k_0)/2] \), where \( k_0 = \min\{k, E\} \). There exists a randomized protocol for \( \text{EqualityTesting} \) length-\( k \) vectors \( x, y \) with Hamming distance \( \text{dist}(x, y) \leq k_0 \) that uses \( r \) rounds, \( O(k + rEk_0^{1/r}) \) bits of communication, and errs with probability \( p_{\text{err}} = 2^{-(E+1)} \).

**Proof.** We begin by giving the parameters \( k_j \) and \( l_j \).

\[
\begin{align*}
k_j &= k_0^{1-j/r}, \\
l_j &= 4Ek_0^{j/r-1}.
\end{align*}
\]

Now fix a phase \( j \in [1, r] \) and suppose at the beginning of phase \( j \) that the number of false positives in \( I_{j-1} \) is at most \( k_{j-1} \). By assumption this holds for \( j = 1 \). The probability that at least \( k_j \) false positives survive phase \( j \) is upper bounded by

\[
\begin{align*}
\left(\frac{k_{j-1}}{k_j}\right)^{2-k_jl_j} &\leq \left(\frac{ek_{j-1}}{k_j}\right)^{k_j} 2^{-k_jl_j} \\
&\leq 2^{2k_j\log(k_{j-1}/k_j)-k_jl_j} e \leq k_0^{1/r} \quad \text{due to } r \leq \frac{\log k_0}{2}. \\
&\leq 2^{-2E}. \\
&\quad \text{Because } \log \frac{k_{j-1}}{k_j} \leq \frac{k_{j-1}}{k_j} = k_0^{1/r} \leq l_j/4.
\end{align*}
\]

Thus, by a union bound, the number of false positives surviving phase \( j \) is strictly less than \( k_j \), for all \( j \in [1, r] \), with probability at least \( 1 - 2^{-(E+1)} \). In particular, there are no false positives at the end since \( k_r = 1 \).

Meanwhile, by Corollary 4.2 the total communication volume is \( O(k + rEk_0^{1/r}) \) since

\[
\sum_{j=1}^{r} k_{j-1}l_j = 4rEk_0^{1/r},
\]

and

\[
\sum_{j=1}^{r} k_{j-1} \log \frac{k}{k_{j-1}} = k_0 \sum_{j=0}^{r-1} \frac{1}{k_0^{j/r}} \left( \log \frac{k}{k_0} + \log k_0^{j/r} \right)
\]

24
\[ \leq 2k_0 \log \frac{k}{k_0} + k_0 \sum_{j=0}^{r-1} \frac{\log k^j}{r} \]

\[ k_0^{1/r} \geq 2^2 \text{ due to } r \leq \frac{\log k_0}{2}. \]

\[ = O(k). \]

Because \( k_0^{1/r} \geq 2^2 \) and \( k_0 \leq k \).

**Proof of Theorem 4.** Applying Theorem 7 and Theorem 8 in sequence, we obtain a \((\log^*(k/E) + r)\)-round randomized protocol for **Equality Testing** on vectors of length \( k \) that errs with probability \( p_{err} = 2^{-E} \) and uses \( O(k + rE \min\{k, E\}^{1/r}) \) bits of communication. When \( E \geq k \) the protocol is obtained directly from Theorem 8 and uses \( O(rEk^{1/r}) \) communication. When \( E < k \) the communication implied by Theorems 7 and 8 is \( O(k + rE^{1+1/r}) = O(k + rEk^{1/r}) \). \( \square \)

### 4.3 An \( O(k + E k^{1/r}) \)-bit **ExistsEqual** Protocol

#### 4.3.1 Overview of the protocol

In this section, we show that we can obtain a \((\log^*(k/E) + r)\)-round, \( O(k + E k^{1/r}) \)-bit protocol for **ExistsEqual**. This matches the lower bound of Theorem 3 asymptotically, when \( E \geq k \). Theorem 7 covers the first part of the protocol, so we assume without loss of generality that \( E \geq k \).

Suppose the inputs \( x \) and \( y \) share no equal coordinates. Imagine writing down all the possible results of the inner product tests in a matrix \( A \) of dimension \((E + \log k) \times k\), where \( A_{ij} \) is “=” if \( x_i, y_i \) pass the \( j \)th inner product test, and “≠” otherwise. By a union bound, with probability \( 1 - 2^{-E} \), each column contains at least one “≠”. Now consider the area above the first “≠” in each column. The probability that this area is at least \( E' \) is, by a union bound, at most

\[ \left( \frac{E' + k - 1}{k - 1} \right) 2^{-E'} < \exp(k \log(e(E' + k)/k) - E'). \] (4)

For \( E' = E + O(k \log(E/k)) = O(E) \), this probability is \( \ll 2^{-E} \). In our analysis it suffices to consider a situation where an adversary can decide the contents of \( A \), subject to the constraint that its error budget (the area above the curve defined by the first “≠” in each column) never exceeds \( E' = O(E) \). The notion of an error budget is also essential for analyzing the protocol of Section 4.4.

In the \( j \)th phase, \( j \geq 1 \), our protocol exposes the fragment of \( A \) consisting of the next \( l_j \) rows of columns in \( I_{j-1} \). The set \( I_j \) consists of those columns without any “≠” exposed so far. The communication budget for phase \( j \) is equal to \( l_j |I_{j-1}| \). In the worst case, the first exposed value in each column of \( I_{j-1} \setminus I_j \) is “≠”, so the adversary spends at least \( l_j |I_j| \) of its error budget in phase \( j \).

If we witness at least one “≠” in every column, we can correctly declare there does not exist an equal coordinate and answer *no*. Otherwise, if the adversary has not exceeded his error budget but there is some column without any “≠”, we answer *yes*. If the adversary ever exhausts his error budget, we terminate the protocol and answer *yes*. Recall that the notion of an error budget tacitly assumed that \( x \) and \( y \) differ in all coordinates. If they do not, the protocol always answers correctly, whether it halts prematurely or not. The probability that the error budget is exhausted when \( x \) and \( y \) differ in all coordinates (a false positive) is \( \ll 2^{-E} \), according to Eqn. (4).

\[ ^8 \text{It appears as if } rE^{1+1/r} \text{ is an improvement over } rEk^{1/r} \text{ when } E < k, \text{ but this is basically an illusion. In light of Remark 11 we can always dedicate } \log^*(k/E) - 2 \text{ rounds to the first part and } r + 2 \text{ rounds to the second part while increasing the communication by } O(k). \text{ When } E \geq k^{1-1/r}, rE^{1+1/r} = \Omega((r + 2)Ek^{1/(r+2)}), \text{ meaning there is no clear benefit to use the } rE^{1+1/r} \text{ expression.} \]
4.3.2 Analysis

In this section we give a formal proof to the following Theorem:

**Theorem 9.** Fix any $k \geq 1$, $E \geq k$, and $r \in [1, (\log k)/2]$. There exists an $r$-round randomized protocol for **ExistsEqual** on vectors of length $k$ that errs with probability $p_{err} = 2^{-(E+1)}$, using $O(Ek^{1/r})$ bits of communication.

**Proof.** The number of tests per coordinate in phase $j$ is $l_j$:

$$l_j = 2E l_j^{j/r-1}.$$

Define $E_j = \sum_{j'=1}^{j} l_{j'}|I_{j'}|$ to be the portion of the error budget spent in phases 1 through $j$. We can express the asymptotic communication cost of the protocol in terms of the error budget as follows.

$$\sum_{j=1}^{r} l_j |I_{j-1}| \leq l_1 |I_0| + k^{1/r} \sum_{j=2}^{r} l_{j-1} |I_{j-1}|$$

$$l_j = k^{1/r} l_{j-1}.$$

$$\leq 2E k^{1/r} + E_{r-1} k^{1/r} \text{ \quad Defn. of } E_{r-1}.$$

Recall that the protocol terminates immediately after phase $j$ if $E_j \geq E'$, which indicates $E_{r-1} < E'$. Hence, the total cost is bounded by

$$\leq (2E + E') k^{1/r} = O(Ek^{1/r}).$$

The protocol can only err if $x$ and $y$ differ in every coordinate. In this case, there are two possible sources of error. The first possibility is that the protocol answers yes because $|I_r| \geq 1$. By a union bound, this happens with probability at most

$$k 2^{-\sum_{j=1}^{r} l_j} \leq k 2^{-E}.$$

The second possibility is that the protocol terminates prematurely and answers yes if $E_j \geq E'$ for some $j \in [1, r]$. The probability of this event occurring is also $\ll 2^{-E}$; see Eqn. (1). This concludes the proof. \qed

**Proof of Theorem 5.** Theorem 5 follows directly by combining Theorem 7 and Theorem 9. \qed

**Remark 2.** By applying the reduction of Theorem 1 to Theorem 9, we conclude that **SetDisjointness** can be solved in $r + 1$ rounds using $O(Ek^{1/r})$ bits of communication. In this particular case we actually do not need Theorem 1; it is possible to solve **SetDisjointness** directly in $r$ rounds with $O(Ek^{1/r})$ communication by an algorithm along the lines of Theorem 9 or [ST13]. Theorem 1 can also be applied to Theorem 8 to yield a **SetIntersection** protocol using $r + 1$ rounds and $O(rE k^{1/r})$ communication, but here we do not see how to solve the problem directly in $r$ rounds. It seems we would need some analogue of Lemma 4.1 tailored to the **SetIntersection** problem.

4.4 A Communication Optimal **EqualityTesting** Protocol

Suppose we want a communication optimal **EqualityTesting** protocol using $O(k + E)$ bits. When $E \geq k$ we need $r = \Omega(\log k)$ rounds, by Theorem 2. In this section, we give a protocol for **EqualityTesting** that uses $O(r)$ rounds (rather than $r$) and $O(Ek^{1/r})$ bits of communication, assuming $E \geq k$. Observe that when $r = \Theta(\log k)$, there is no (asymptotic) difference between $r$ rounds and $O(r)$ rounds as this only influences the leading constant in the communication volume.
4.4.1 Overview of the protocol

The protocol uses the concept of an error budget introduced in Section 4.3. To shave the factor \( r \) off the communication volume, we cannot afford to use \( E k^{j/r-1} \) test bits for each coordinate that participates in phase \( j \). Consequently, we cannot guarantee with high probability (say \( 1 - 2^{-E/r} \)) that the number of false positives is less than \( k^{1-3/r} \).

Our protocol needs to be able to respond to the rare event that the number of false positives in \( I_j \) is larger than \( k_j \). Notice that this type of error cannot be detected in the first \( j \) phases, and is not easily detectable in the following phases. The danger in the number of false positives in \( I_j \) exceeding \( k_j \) is that when the test bits for phase \( j+1 \) are exchanged using Lemma 4.1, the protocol may silently fail, with all test bits potentially corrupted.

To address these challenges, Alice and Bob each keep a history of all the test bits they have generated so far. They also keep a history of the test bits they have received from the other party, which may have been corrupted. Define \( T_A \) and \( T_B \) to be the true history of the test bits generated by Alice and Bob, respectively. Define \( T_B^{(A)} \) to be what Alice believes Bob’s history to be, and define \( T_A^{(B)} \) analogously. Observe that if every invocation of Lemma 4.1 succeeds, then \( T_A = T_A^{(B)} \) and \( T_B = T_B^{(A)} \).

To detect inconsistencies, after Alice and Bob generate and exchange their test bits for phase \( j \), they accumulate their views of the history into strings \( T^{(A)} = T_A \circ T_B^{(A)} \) and \( T^{(B)} = T_A^{(B)} \circ T_B \), respectively, where \( \circ \) is the concatenation operator, and verify that \( T^{(A)} = T^{(B)} \) with a certain number of inner product tests. This is called a history check. If the history check passes, they can proceed to phase \( j+1 \). If the history check fails then the results of phase \( j \) are junk, and we can infer that one of two types of low probability events occurred in phase \( j-1 \). The first possibility is that the test bits at phase \( j-1 \) were exchanged successfully (and consequently, the history check succeeded), but \( I_{j-1} \) contains more than \( k_{j-1} \) false positives. The second possibility is that Alice’s and Bob’s histories were already inconsistent at phase \( j-1 \), but the phase-(\( j-1 \)) history check failed to detect this. Notice that Alice and Bob cannot detect which of these types of errors occurred. In either case, we must undo the effects of phases \( j \) and \( j-1 \) and restart the protocol at the beginning of phase \( j-1 \). It may be that the history check then fails at the re-execution of phase \( j-1 \), in which case we would continue to rewind to the beginning of phase \( j-2 \), and so on. Being able to rewind multiple phases is important because we do not know which phase suffered the first error.

Both parties maintain an empirical error meter \( E'' \) that measures the sum of logarithms of probabilities of low probability (error) events that have been detected. If the error meter ever exceeds the error budget \( E'' = \Theta(E) \) we terminate the protocol, which we show occurs with probability \( \lesssim 2^{-E} \). Thus, the process above (proceeding iteratively with phases, undoing and redoing them when errors are detected) must end by either successfully completing phase \( r \) or exceeding the error budget.

If Alice and Bob successfully finish phase \( r \), we are still not done. This is because an error can happen in the later phases but we do not have sufficiently high \( (1 - 2^{-E}) \) confidence that they all succeeded. To build this confidence, Alice and Bob do inner product tests on the whole history, gradually increasing their number until \( \Theta(E) \) tests have been done. If one of these history checks fails, we increase the error meter \( E'' \) appropriately and rewind the protocol to a suitable phase \( j \) in the first stage of the protocol.

Let us make every step of this protocol more quantitatively precise.

- The protocol has two stages, the Refutation Stage (in which potential equalities are refuted)
and the Verification Stage, each consisting of a series of phases. Although the Refutation Stage logically precedes the Verification Stage, because phases can be undone, an execution of the protocol may oscillate between Refutation and Verification multiple times.

- The Refutation Stage is similar to the protocol in Section 4.2 except Alice and Bob will verify whether the messages conveyed by Lemma 4.1 are successfully received with further inner product tests. The budget of phase \( j \) is

\[
B_j = \frac{E_{k_0}^{1/r}}{\min\{j^2, r\}}.
\]

Observe that \( \sum_{j'=1}^{r} B_j = O(E_{k_0}^{1/r}) \). Thus, in phase \( j \), we perform \( l_j = B_j/k_{j-1} \) independent inner product tests on each coordinate in \( I_{j-1} \). As usual, \( I_0 \) is initially \([k]\) and \( k_j = k_{0}^{1-j/r} \), where \( k_0 \leq E \). All histories \( T_A, T_B, T_B^{(A)}, T_A^{(B)} \) are initially empty, and the error meter \( E'' \) is initially zero.

- Phase \( j \) has two steps, the test step and the history check step. In the test step, Alice and Bob conduct inner product tests as in Section 4.2, i.e., they generate \( l_j \) test bits for each coordinate in \( I_{j-1} \) and exchange them using Lemma 4.1 assuming their Hamming distance is at most \( k_{j-1} \). Alice appends the test bits she generates onto the history \( T_A \), and appends the test bits she receives from Bob onto \( T_B^{(A)} \). Bob does likewise. In the history check step, they use \( B_j \) independent inner product tests to check whether \( T^{(A)} = T^{(B)} \), where \( T^{(A)} = T_A \circ T_B^{(A)} \), and \( T^{(B)} = T_A^{(B)} \circ T_B \). The history check fails if they detect inequality and passes otherwise. Since \( B_j \) is, in general, less than \( E \), we are still skeptical of history checks that pass.

- If the history check for phase \( j \) passes, Alice and Bob proceed to phase \( j+1 \), or proceed to the Verification Stage if \( j = r \). Otherwise, an error has been detected: either the number of false positives in \( I_{j-1} \) is at least \( k_{j-1} \), or the history check at phase \( j-1 \) mistakenly passed. The latter occurs with probability \( \exp(-B_{j-1}) \) and we show the former occurs with probability \( \exp(-3k_0^{-1/r} B_{j-1}/4) \). Not knowing which occurred, we increment the error meter \( E'' \) by \( k_0^{-1/r} B_{j-1}/2 \) due to a union bound. If \( E'' \) exceeds the error budget \( E'' = cE \) then we halt, where \( c \geq 2 \) is a suitable constant. Otherwise we retract the effects of phases \( j \) and \( j-1 \) and continue the protocol at the beginning of phase \( j-1 \), with “fresh” random bits so as not to recreate previous errors.

- Observe that after phase \( r \) of the Refutation Stage, each coordinate in \( I_r \) has only passed about \( B_r/k_{r-1} = E/r \) inner product tests, which is not high enough. Before the Verification Stage begins, Alice and Bob each generate \( E' \) test bits for each coordinate in \( I_r \) and append them to \( T^{(A)} \) and \( T^{(B)} \). (This can be viewed as a degenerate instantiation of Lemma 4.1 with \( d = 0 \), which requires no communication.) If there are no false positives in \( I_r \), these test bits must be identical.

- In the Verification Stage the phases are indexed in reverse order: \( r, r-1, ..., 1 \). In each successive phase \( j \), Alice and Bob test the equality \( T^{(A)} = T^{(B)} \) with \( B_j \) independent inner product tests. This process stops if it passes a total of \( E' \) tests, in which case they report that \( x \) and \( y \) are equal on \( I_r \) and not equal on \([k]\setminus I_r \), or some Verification phase \( j \) detects
that \( T^{(A)} \neq T^{(B)} \). In this case, we know Verification phases \( r, r-1, \ldots, j+1 \) passed in error, and that there must also have been an error in Refutation phase \( r \). Therefore, Alice and Bob increment \( E'' \) by \( k_0^{-1/r} B_r/2 + \sum_{j'=j+1}^{r'} B_{j'} \) and halt if \( E'' \geq E' \). If not, they rewind the execution of the protocol to phase \( j \) of the Refutation Stage and continue.

Algorithm 1 recapitulates this description in the form of pseudocode, from the perspective of Alice. Here \( T^{(A)}[j, i] \) refers to the sequence of Alice's test bits in \( T^{(A)} \) for the \( i \)th coordinate produced in the most recent execution of phase \( j \), and \( T^{(A)}[j_1 \cdots j_2, i] \) refers to the test bits generated from phase \( j_1 \) to phase \( j_2 \). Phase \( r+1 \) refers to the \( E' \times |I_r| \) test bits generated between the Refutation and Verification stages. \( T^{(A)}[j, i] \) refers to the concatenation of \( T^{(A)}[j, i] \) and \( T^{(A)}[j, i] \). What remains is to analyze the error probability of the protocol.

### 4.4.2 Analysis

To prove Theorem 6, it suffices to prove the following Theorem 10.

**Theorem 10.** Fix any \( k \geq 1, E \geq 1, \) and \( r \in [1, (\log k_0)/6] \), where \( k_0 = \min\{k, E\} \). There exists a randomized protocol for Equality Testing length-\( k \) vectors \( x, y \) with Hamming distance \( \text{dist}(x, y) \leq k_0 \) that uses \( O(r) \) rounds, \( O(k + E k_0^{1/r}) \) bits of communication, and errs with probability \( p_{\text{err}} = 2^{-E+1} \).

The protocol of Lemma 4.1 fails if Bob does not generate the correct \( x' = x \), which indicates that the precondition is not met, i.e., \( \text{dist}(x, y) > d \). Refutation phase \( j \) fails if the condition in line 29 is not satisfied and the else branch at line 39 is executed in order to resume the protocol from phase \( j - 1 \). Similarly, we say Verification phase \( j \) fails if the condition in line 47 is not satisfied, which also indicates the else branch at line 51 is executed and the protocol is resumed from Refutation phase \( j \).

**Algorithm 1** An Equality Testing protocol for Theorem 10 (from the perspective of Alice).

1: procedure EqualityTesting \( \triangleright \) main procedure

56: end procedure
Recall that there are two types of errors at phase 𝐴.

Lemma 4.4. Fix any 𝑗 ∈ [2, 𝑟]. If phase 𝑗 of the Refutation Stage fails, then the outcome of the most recent execution of phase 𝑗 − 1 happened with probability at most \(\exp(-k_0^{-1/r}B_{j-1}/2)\).

Proof. Recall that there are two types of errors at phase 𝑗 − 1. If the (𝑗 − 1)th history check erroneously passed, this occurred with probability \(\exp(-B_{j-1})\). The probability that more than \(k_{j-1}\) false positives survive in \(I_{j-1}\) is less than

\[
\left( \frac{k_0}{k_{j-1}} \right) \cdot 2^{-k_{j-1}l_{j-1}} \leq \left( \frac{ek_0}{k_{j-1}} \right)^{k_{j-1}l_{j-1}} \leq 2^{2^{k_{j-1}l_{j-1} + \log(k_0/k_{j-1}) - k_{j-1}l_{j-1}}} \leq 2^{-3l_{j-1}k_{j-1}/4},
\]

where the last step follows from the inequality

\[
2 \log \frac{k_0}{k_{j-1}} = 2(j - 1) \log k_0^{1/r} \leq \frac{8(j - 1) \log k_0^{1/r}}{4(j - 1)^2},
\]

Because \(8x^3 \leq 8^x\) for \(x \in \mathbb{N}\).

\[
\leq \frac{k_0^{(j-1)/r}}{4(j - 1)^2} \leq \frac{B_{j-1}}{4k_{j-2}} \leq \frac{l_{j-1}}{4}.
\]

Combining the above two cases, by a union bound, the outcome of the most recent execution of phase 𝑗 − 1 of the Refutation Stage happens with probability at most \(\exp(-B_{j-1}) + \exp(-3k_0^{-1/r}B_{j-1}/4) \leq \exp(-k_0^{-1/r}B_{j-1}/2)\), as claimed.

Lemma 4.5. Fix any 𝑗 ∈ [1, 𝑟]. If phase 𝑗 of the Verification Stage fails, then the outcomes of the most recent execution of phases \(r, r-1, \ldots, j + 1\) of the Verification Stage and phase 𝑟 of the Refutation Stage happened with overall probability at most \(\exp(-k_0^{-1/r}B_r/2 - \sum_{j'=j+1}^{r} B_{j'})\).

Proof. Notice that the failure of Verification phase 𝑗 means all previous Verification phases \(r, r-1, \ldots, j+1\) failed to detect an inconsistency in the history, which occurs with probability \(\exp(-\sum_{j'=j+1}^{r} B_{j'})\). Meanwhile, the inconsistency is caused by an error of some type in Refutation phase 𝑟, which, according to Lemma 4.4, occurs with probability at most \(\exp(-k_0^{-1/r}B_r/2)\). Therefore, the outcomes of the most recent execution of Verification phases \(r, r-1, \ldots, j+1\) and Refutation phase 𝑟 happened with overall probability at most \(\exp(-k_0^{-1/r}B_r/2 - \sum_{j'=j+1}^{r} B_{j'})\).
Lemma 4.6. Algorithm \[ \] executes \( O(r) \) extra Refutation/Verification phases and uses \( O(k + Ek_0^{1/r}) \) extra bits of communication.

Proof. We first consider the total number of extra phases. Each failure of Refutation phase \( j \) uses at least \( k_0^{-1/r} B_{j-1}/2 \geq E/(2r) \) of the error budget and causes the re-execution of two phases, namely \( j - 1 \) and \( j \). Similarly, each failure of Verification phase \( j \) uses \( k_0^{-1/r} B_r/2 + \sum_{j'=j+1}^r B_{j'} \geq (r - j + 1)E/(2r) \) of the error budget and causes the re-execution of \( 2(r - j + 1) \) phases. Thus, the total number of extra phases is at most \( 4cr = O(r) \), where the error budget \( E' = cE \).

Turning to the overall extra communication, notice that phase \( j \) of the Refutation Stage has communication volume \( O(B_j + k_{j-1} \log(k/k_{j-1})) \) and phase \( j \) of the Verification Stage has communication volume \( O(B_j) \). For any \( j \in [2, r] \), also notice that \( B_{j-1}/B_j \leq j^2/(j - 1)^2 \leq 4 \leq k_0^{1/r} \). Thus, the communication caused by each failure is at most \( O(k_0^{1/r}) \) times the error budget spent by that failure, if we temporarily ignore the \( k_{j-1} \log(k/k_{j-1}) \) term.

In order to upper bound the communication contributed by the \( k_{j-1} \log(k/k_{j-1}) \) term, observe that Refutation phase \( j \) can only be repeated \( O(j^2) \) times before the error budget is exhausted. Thus, the overall extra communication is upper bounded by \( O(k + Ek_0^{1/r}) \) since

\[
O(k_0^{1/r}) \cdot E' + \sum_{j=1}^r O(j^2) \cdot k_{j-1} \log \frac{k}{k_{j-1}}
= O(k_0^{1/r}) \cdot E' + k_0 \sum_{j=1}^r \frac{O(j^2)}{k_0^{(j-1)/r}} \left( \log \frac{k}{k_0} + \log k_0^{(j-1)/r} \right)
= O(k_0^{1/r}) \cdot E' + k_0 \log \frac{k}{k_0} \sum_{j=1}^r \frac{O(j^2)}{k_0^{(j-1)/r}} + k_0 \sum_{j=1}^r \frac{O(j^2) \cdot \log k_0^{(j-1)/r}}{k_0^{(j-1)/r}}
= O(k + Ek_0^{1/r}).
\]

Because \( k_0^{1/r} \geq 2^6 \) and \( k_0 \leq k \).

\[ \square \]

Now we are ready to prove Theorem 10.

Proof of Theorem 10. If there are no errors, Algorithm \[ \] has at most \( 2r \) phases and uses \( O(\sum_{j=1}^r (B_j + k_{j-1} \log(k/k_{j-1}))) = O(k + Ek_0^{1/r}) \) communication, where each phase can be implemented in \( O(1) \) rounds. Together with Lemma 4.6, we have shown that it is an \( O(r) \)-round randomized Equality Testing protocol using \( O(k + Ek_0^{1/r}) \) bits of communication. Thus, it suffices to calculate the error probability of the protocol.

Consider a possible execution of the protocol, i.e., the sequence of the Refutation/Verification phases that are performed. It can be represented by a unique 0-1 string of length at most \( 4cr + 2r \) (by the proof of Lemma 4.6) such that each “1” corresponds to a failed phase. In particular, each execution of the protocol that terminates prematurely because \( E'' \geq E' \) is represented as a 0-1 string, which occurs with probability at most \( 2^{-E'} \), by Lemmas 4.4 and 4.5. Hence the overall probability of terminating prematurely is \( 2^{4cr+2r} \cdot 2^{-E'} \).

An error can also be caused by at least one false positive surviving all \( E' \) independent inner product tests generated after Refutation phase \( r \). The probability of this happening is at most \( k_0 2^{-E'} \). The last possible source of error is that all Verification phases fail to detect the inequality...
\(T^{(A)} \neq T^{(B)}\). According to line 18, the probability of this happening is at most 2\(^{-E'}\). Hence, the overall probability of error is upper bounded by
\[
2^{4r+2r} \cdot 2^{-E'} + k_0 2^{-E'} + 2^{-E'} = \text{poly}(k_0)2^{-E'},
\]
which is at most 2\(^{-E}\) for, say, \(E' = 2E\). This concludes the proof. \(\square\)

Proof of Theorem 6. Theorem 6 subsequently follows by applying Theorem 7 and Theorem 10 in sequence.

5 Distributed Triangle Enumeration

One way to solve local triangle enumeration in the CONGEST model is to execute, in parallel, a SetIntersection protocol across every edge of the graph, where the set associated with a vertex is a list of its neighbors. Since there are at most \(\Delta n/2\) edges, we need the SetIntersection error probability to be 2\(^{-E}\), \(E = \Theta(\log n)\), in order to guarantee a global success probability of 1 – 1/poly(n). Our lower bound says any algorithm taking this approach must take \(\Omega((\Delta + E\Delta^{1/r})/\log n + r)\) rounds since each round of CONGEST allows for one O(\(\log n\))-bit message. The hardest situation seems to be when \(\Delta = E = \Theta(\log n)\), in which case the optimum choice is to set \(r = \log \Delta\), making the triangle enumeration algorithm run in \(O(\log \Delta) = O(\log \log n)\) time. In Theorem 11, we show that it is possible to handle this situation exponentially faster, in \(O(\log \log \Delta) = O(\log \log \log n)\) time, and in general, to solve local triangle enumeration [IG17] in optimal \(O(\Delta/\log n)\) time so long as \(\Delta > \log n \log \log n\).

Theorem 11. Local triangle enumeration can be solved in a CONGEST network \(G = (V, E)\) with maximum degree \(\Delta\) in \(O(\Delta/\log n + \log \log \Delta)\) rounds with probability 1 – 1/poly(n). This is optimal for all \(\Delta = \Omega((\log n \log \log n)\).

Proof. The algorithm consists of \(\min\{\log \log \Delta, \log \log \log n\}\) phases. The goal of the first phase is to transform the original triangle enumeration problem into one with maximum degree \(\Delta_1 < (\log n)^{o(1)}\), in \(O(\log^* n)\) rounds of communication. The goal of every subsequent phase is to reduce the maximum degree from \(\Delta' \leq \sqrt{\log n} \to \sqrt{\Delta'}\), in \(O(1)\) rounds of communication. Thus, the total number of rounds is \(O(\log \log \Delta)\) rounds if the first round is skipped, and \(O(\log^* n + \log \log(\Delta_1)) = O(\log \log \log n)\) otherwise.

Phase One. Suppose \(\Delta \geq \sqrt{\log n}\). Each vertex \(u\) is identified with the set \(A_u = \{ID(v) \mid \{v, u\} \in E\}\) having size \(\Delta\). For each \(\{u, v\} \in E\) we reduce SetIntersection to EqualityTesting by applying Theorem 11 then run the two-party EqualityTesting protocol of Theorem 11 with \(k = \max\{\Delta, \log n\}, r = \log^* n\), and \(E = r^{-1}k^{1-1/r}\). (I.e., if \(\Delta < \log n\) we imagine padding each set to size \(\log n\) with dummy elements.) One undesirable property of this protocol is that it can fail “silently” if the preconditions of Lemma 11.1 are not met. When the Hamming distance between two strings exceeds the threshold \(d\), Bob generates a garbage string \(x' \neq x\) but fails to detect this. To rectify this problem, we change the Lemma 11.1 protocol slightly: Alice sends the color \(\phi(x)\) of her string, as well as an \(O(\log n)\)-bit hash \(h(x)\). Bob reconstructs \(x'\) as usual and terminates the protocol if \(h(x) \neq h(x')\). Clearly the probability of an undetected failure (i.e., \(x \neq x'\) but \(h(x) = h(x')\)) is 1/poly(n). Define \(G_1 = (V, E_1)\) such that \(\{u, v\} \in E_1\) iff the SetIntersection protocol over \(\{u, v\}\) detected a failure. In other words, with high probability, all triangles in \(G\) have been discovered,
except for those contained entirely inside $G_1$. The probability that any particular edge appears in $E_1$ is $2^{-E} = 2^{-k^{1-1/\log^* n}/\log^* n}$ and independent of all other edges. In particular, if $\Delta \gg (\log n)^{1+1/\log^* n}$ then no errors occur, with probability $1 - 1/poly(n)$. Define $\Delta_1$ to be the maximum degree in $G_1$. Thus,

$$\Pr[\Delta_1 \geq (\log n)^{2\epsilon}] \leq n \cdot \left(\frac{\Delta}{(\log n)^{2\epsilon}}\right) \cdot (2^{-E})^{(\log n)^{2\epsilon}}$$

$$\epsilon = 1/r = 1/\log^* n$$

$$\leq n \cdot \exp(O((\log n)^{2\epsilon} \log \log n)) \cdot 2^{-\epsilon(\log n)^{1-\epsilon} \cdot (\log n)^{2\epsilon}}$$

$$\leq 1/poly(n).$$

**Phases Two and Above.** Suppose that at some round, we have detected all triangles except for those contained in some subgraph $G' = (V, E')$ having maximum degree $\Delta' < \sqrt{\log n}$. Express $\Delta'$ as $(\log n)^{\gamma}$, where $\gamma < 1/2$. We execute the EqualityTesting protocol of Theorem 8 with $k = \Delta'$, $r = 2$, and $E = C(\log n)^{1-\gamma/2}$ for a sufficiently large constant $C$. Note that $1 - \gamma/2 > \gamma$, so $E > k$, as required by Theorem 8. The protocol takes $O(Ek^{1/2}/\log n + r) = O(1)$ rounds since the communication volume is $O(Ek^{1/2}) = O(\log n)$ and $r = 2$. Let $G''$ be the subgraph of $G'$ consisting of edges whose protocols detected a failure and $\Delta''$ be the maximum degree in $G''$. Once again,

$$\Pr[\Delta'' \geq (\log n)^{\gamma/2}] \leq n \cdot \left(\frac{\Delta'}{(\log n)^{\gamma/2}}\right) \cdot (2^{-E})^{(\log n)^{\gamma/2}}$$

$$\leq n \cdot \exp(O((\log n)^{\gamma/2} \log \log n)) \cdot 2^{-C(\log n)^{1-\gamma/2} \cdot (\log n)^{\gamma/2}}$$

$$\leq 1/poly(n).$$

Thus, once $\Delta \leq \sqrt{\log n}$, $\log \log \Delta \leq \log \log \log n - 1$ of these 2-round phases suffice to find all remaining triangles in $G$.

Theorem 11 depends critically on the duality between edges and SetIntersection instances, and between edge endpoints and elements of sets. In particular, when an execution of a SetIntersection over $\{u, v\}$ is successful, this effectively removes $\{u, v\}$ from the graph, thereby removing many occurrences of $\text{ID}(u)$ and $\text{ID}(v)$ from adjacent sets.

Consider a slightly more general situation where we have a graph of arboricity $\lambda$ (but unbounded $\Delta$), witnessed by a given acyclic orientation having out-degree at most $\lambda$. Redefine the set $A_u$ to be the set of out-neighbors of $u$.

$$A_u = \{\text{ID}(v) \mid \{u, v\} \in E \text{ with orientation } u \to v\}.$$  

By definition $|A_u| \leq \lambda$. Because the orientation is acyclic, every triangle on $\{x, y, z\}$ is (up to renaming) oriented as $x \to y$, $x \to z$, $y \to z$. Thus, it will only be detectable by the SetIntersection instance associated with $\{x, y\}$.

**Theorem 12.** Let $G = (V, E)$ be a CONGEST network equipped with an acyclic orientation with outdegree at most $\lambda$. We can solve local triangle enumeration on $G$ in $O(\lambda/\log n + \log \lambda)$ time.

**Proof.** We apply Theorem 11 to reduce each SetIntersection instance to an EqualityTesting instance, then apply Theorem 11 with $E = \Theta(\log n)$ and $r = \log \lambda$ to solve each with $O(\lambda + El^{1/r}) = O(\lambda + E)$ communication in $O((\lambda + E)/\log n + r) = O(\lambda/\log n + \log \lambda)$ time. Note that the dependence on $\lambda$ here is exponentially worse than the dependence on $\Delta$ in Theorem 11.
It may be that $G$ is known to have arboricity $\lambda$, but an acyclic orientation is unavailable. The well known “peeling algorithm” (see [CNS85] or [BE10]) computes a $C\lambda$ orientation in $O(\log_C n)$ time for $C$ sufficiently large, say $C \geq 3$. Using this algorithm as a preprocessing step, we can solve local triangle enumeration optimally when $\lambda = \Omega(\log^2 n)$.

**Theorem 13.** Let $G = (V, E)$ be a CONGEST network having arboricity $\lambda$ (with no upper bound on $\Delta$). Local triangle enumeration can be solved in optimal $O(\lambda/\log n)$ time when $\lambda = \Omega(\log^2 n)$, and sublogarithmic time $O(\log n/\log(\log^2 n/\lambda))$ otherwise.

**Proof.** The algorithm computes a $\gamma \cdot \lambda$ orientation in $O(\log n)$ time and then applies Theorem 12 to solve local triangle enumeration in $O(\gamma\lambda/\log n + \log(\gamma\lambda))$ time. The only question is how to set $\gamma$. If $\lambda = \Omega(\log^2 n)$ we set $\gamma = 3$, making the total time $O(\lambda/\log n)$, which is optimal [IG17]. Otherwise we choose $\gamma$ to balance the $\log\gamma n$ and $\gamma\lambda/\log n$ terms, so that

$$\gamma \log\gamma = \log^2 n/\lambda$$

Thus, the total running time is slightly sublogarithmic $O(\log n/\log(\log^2 n/\lambda))$. Specifically, it is $O(\log n/\log \log n)$ whenever $\lambda < \log^{2-\epsilon} n$.

6 Conclusions and Open Problems

We have established a new three-way tradeoff between rounds, communication, and error probability for many fundamental problems in communication complexity such as SetDisjointness and EqualityTesting. Our lower bound is largely incomparable to the round-communication lower bounds of [ST13] [BCK+16], and stylistically very different from both [ST13] and [BCK+16]. We believe that our method can be extended to recover Sağlam and Tardos’s [ST13] tradeoff (in the constant error probability regime), but with a more “direct” proof that avoids some technical difficulties arising from their round-elimination technique. It is still open whether EqualityTesting can be solved in $r$ rounds with precisely $O(Ek^{1/r})$ communication and error probability $2^{-E} < 2^{-k}$. Our algorithms match this lower bound only when $r = O(1)$ or $r = \Omega(\log k)$, or for any $r$ when solving the easier ExistsEqual problem.

We developed some CONGEST algorithms for triangle enumeration that employ two-party SetIntersection protocols. It is known that this strategy is suboptimal when $\Delta \gg n^{1/3}$ [CPZ19] [CS19]. However, for the local triangle enumeration problem our $O(\Delta/\log n + \log \log \Delta)$ algorithm is optimal [IG17] for every $\Delta = \Omega(\log n \log \log \log n)$. Whether there are faster algorithms for triangle detection is an intriguing open problem. It is known that 1-round LOCAL algorithms must send messages of $\Omega(\Delta \log n)$ bits deterministically [ACKL17] or $\Omega(\Delta)$ bits randomized [FGKO18]. Even for 2-round triangle detection algorithms, there are no nontrivial communication lower bounds known.

A Reductions and Near Equivalences

Brody et al. [BCK+16] proved that SetIntersection on sets of size $k$ is reducible to EqualityTesting on vectors of length $O(k)$, at the cost of one round and $O(k)$ bits of communication. However, the reduction is randomized and fails with probability at least $\exp(-\tilde{O}(\sqrt{k}))$. This is the probability that when $k$ balls are thrown uniformly at random into $k$ bins, some bin contains $\omega(\sqrt{k})$ balls.

Recall the statement of Theorem 1:

\[
\text{Eq}(k, r, p_{\text{err}}) \leq \text{SetInt}(k, r, p_{\text{err}}),
\]
\[
\exists \text{Eq}(k, r, p_{\text{err}}) \leq \text{SetDisj}(k, r, p_{\text{err}}),
\]
\[
\text{SetDisj}(k, r + 1, p_{\text{err}}) \leq \exists \text{Eq}(k, r, p_{\text{err}}) + \zeta,
\]
\[
\text{SetInt}(k, r + 1, p_{\text{err}}) \leq \text{Eq}(k, r, p_{\text{err}}) + \zeta,
\]

where $\zeta = O(k + \log \log p_{\text{err}}^{-1})$. In other words, under any error regime $p_{\text{err}}$, the communication complexity of SetIntersection and EqualityTesting are the same, up to one round and $O(k + \log \log p_{\text{err}}^{-1})$ bits of communication, and that the same relationship holds between SetDisjointness and ExistsEqual.

The proof is inspired by the probabilistic reduction of Brody et al. [BCK+16], but uses succinct encodings of perfect hash functions rather than random hash functions.

Proof of Theorem 1. The leftmost inequalities have been observed before [ST13, BCK+16]. Given inputs $x, y$ to ExistsEqual or EqualityTesting, Alice and Bob generate sets $A = \{(1, x_1), \ldots, (k, x_k)\}$ and $B = \{(1, y_1), \ldots, (k, y_k)\}$ before the first round of communication and then proceed to solve SetIntersection or SetDisjointness on $(A, B)$. Knowing $A \cap B$ or whether $A \cap B = \emptyset$ clearly allows them to determine the correct output of EqualityTesting or ExistsEqual on $(x, y)$.

The reverse direction is slightly more complicated. Let $(A, B)$ be the instance of SetIntersection or SetDisjointness over a universe $U$ with size at most $|U| = O(k^2/p_{\text{err}})$. Alice examines her set $A$, and picks a perfect hash function $h : U \mapsto [k]$ for $A$, i.e., $h$ is injective on $A$. This can be done in $O(k)$ time, in expectation, using only private randomness. In principle Alice could do this step deterministically, given sufficient time.) Most importantly, $h$ can be described using $O(k + \log \log |U|) = O(k + \log \log p_{\text{err}}^{-1})$ bits [SS90], using a variant of the Fredman-Komlós-Szemerédi [FKS84] 2-level perfect hashing scheme [1]. Alice sends the $O(k + \log \log p_{\text{err}}^{-1})$-bit description of $h$ to Bob. Bob calculates $B_j = B \cap h^{-1}(j)$ and responds to Alice with the distribution $|B_0|, |B_1|, \ldots, |B_{k-1}|$, which takes at most $2k$ bits. They can now generate an instance of Equality Testing where the $k$ equality tests are the pairs $A_0 \times B_0, A_1 \times B_1, \ldots, A_{k-1} \times B_{k-1}$. By construction, $A_j = A \cap h^{-1}(j)$ is a 1-element set. There is clearly a 1-1 correspondence between equal pairs and

---

We sketch how the encoding of $h$ works, for completeness. First, pick a function $h' : U \mapsto [O(k^2)]$ that is collision-free on $A$. Friedman et al. [FKS84] proved that a function of the form $h'(x) = (ax \mod p) \mod O(k^2)$ works with constant probability, where $p = \Omega(k^2 \log |U|)$ is prime and $a \in [0, p)$ is random. Pick another function $h_* : [O(k^2)] \mapsto [k]$ that has at most twice the expected number of collisions on $A$, namely $2 \cdot (\frac{k}{2})/k < k$, and partition $A$ into $k$ buckets $A_j = A \cap h_*^{-1}(j)$. The sizes $|A_0|, |A_1|, \ldots, |A_{k-1}|$ can be encoded with $2k$ bits. We now pick $O(\log k)$ pairwise independent hash functions $h_1, h_2, \ldots, h_{\log(k^2)} : [O(k^2)] \mapsto [O(k^2)]$. For each bucket $A_j$, we define $h_{(j)}^{(i)}$ to be the function with the minimum $i$ for which $h_{(j)}^{(i)}(x) = h_{(j)}(x) \mod |A_j|^2$ is injective on $A_j$. In order to encode which function $h_{(j)}^{(i)}$ is (given that $h_1, \ldots, h_{\log(k^2)}$ are fixed and that $|A_j|$ is known), we simply need to write $i$ in unary, i.e., using the bit-string $0^{i-1}1$. This takes less than 2 bits per $j$ in expectation since each $h_i$ is collision-free on $A_j$ with probability at least $1/2$. Combining $h', h_1, |A_0|, \ldots, |A_{k-1}|$ and $h_{(0)}, \ldots, h_{(k-1)}$ into a single injective function from $U \mapsto [O(k)]$ is straightforward, and done exactly as in [FKS84]. By marking which elements in this range are actually used ($O(k)$ more bits), we can generate the perfect $h : U \mapsto [k]$ whose range has size precisely $k$. Encoding $h'$ takes $O(\log k + \log \log |U|)$ bits and encoding $h_*$ takes $O(\log k)$ bits. The distribution $|A_0|, \ldots, |A_{k-1}|$ can be encoded with $2k$ bits. The functions $h_1, \ldots, h_{\log(k^2)}$ can be encoded in $O(\log^2 k)$ bits, and the functions $h_{(0)}, \ldots, h_{(k-1)}$ with less than $2k$ bits in expectation.
elements in $A \cap B$. We have Bob speak first in the \texttt{EqualityTesting/ExistsEqual} protocol; thus, the overhead for this reduction is just 1 round of communication and $O(k + \log \log p_{\text{err}}^{-1})$ bits.  \qed
