Abstract
We study the problem of estimating multiple linear regression equations for the purpose of both prediction and variable selection. Following recent work on multi-task learning [Argyriou et al. 2008], we assume that the regression vectors share the same sparsity pattern. This means that the set of relevant predictor variables is the same across the different equations. This assumption leads us to consider the Group Lasso as a candidate estimation method. We show that this estimator enjoys nice sparsity oracle inequalities and variable selection properties. The results hold under a certain restricted eigenvalue condition and a coherence condition on the design matrix, which naturally extend recent work in Bickel et al. [2007], Lounici [2008]. In particular, in the multi-task learning scenario, in which the number of tasks can grow, we are able to remove completely the effect of the number of predictor variables in the bounds. Finally, we show how our results can be extended to more general noise distributions, of which we only require the variance to be finite.
1 Introduction

We study the problem of estimating multiple regression equations under sparsity assumptions on the underlying regression coefficients. More precisely, we consider multiple Gaussian regression models,

\[ y_1 = X_1 \beta^*_1 + W_1 \\
\vdots \\
y_T = X_T \beta^*_T + W_T \]

(1.1)

where, for each \( t = 1, \ldots, T \), we let \( X_t \) be a prescribed \( n \times M \) design matrix, \( \beta^*_t \) the unknown vector of regression coefficients and \( y_t \) an \( n \)-dimensional vector of observations. We assume that \( W_1, \ldots, W_T \) are i.i.d. zero mean random vectors.

We are interested in estimation methods which work well even when the number of parameters in each equation is much larger than the number of observations, that is, \( M \gg n \). This situation may arise in many practical applications in which the predictor variables are inherently high dimensional, or it may be “costly” to observe response variables, due to difficult experimental procedures, see, for example Argyriou et al. [2008] for a discussion.

Examples in which this estimation problem is relevant range from multi-task learning Argyriou et al. [2008], Cavallanti et al. [2008], Maurer [2006], Obozinski et al. [2008] and conjoint analysis (see, for example, Evgeniou et al. [2007], Lenk et al. [1996] and references therein) to longitudinal data analysis Diggle [2002] as well as the analysis of panel data Hsiao [2003], Wooldridge [2002], among others. In particular, multi-task learning provides a main motivation for our study. In that setting each regression equation corresponds to a different learning task (the classification case can be treated similarly); in addition to the requirement that \( M \gg n \), we are also interested in the case that the number of tasks \( T \) is much larger than \( n \). Following Argyriou et al. [2008] we assume that there are only few common important variables which are shared by the tasks. A general goal of this paper is to study the implications of this assumption from a statistical learning viewpoint, in particular, to quantify the advantage provided by the large number of tasks to learn both the underlying vectors \( \beta^*_1, \ldots, \beta^*_T \) as well as to select common variables shared by the tasks.

Our study pertains and draws substantial ideas from the recently developed area of compressed sensing and sparse estimation (or sparse recovery), see Bickel et al. [2007], Candès and Tao [2005], Donoho et al. [2006] and references therein. A central problem studied therein is that of estimating the parameters of a (single) Gaussian regression model. Here, the term “sparse” means that most of the components of the underlying \( M \)-dimensional regression vector are equal to zero. A main motivation for sparse estimation comes from the observation that in many practical applications \( M \) is much larger than the number \( n \) of observations but the underlying model is (approximately) sparse, see Candès and Tao [2005], Donoho et al. [2006] and references therein. Under this circumstance ordinary least squares will not work. A more appropriate method for sparse estimation is the \( \ell_1 \)-norm penalized least squares method, which is commonly referred to as the Lasso method. In fact, it has been recently shown by different authors, under different conditions on the design matrix, that the Lasso satisfies sparsity oracle inequalities, see Bickel et al. [2007], Bunea et al. [2007a,b], van de Geer [2008] and references
therein. Closest to our study in this paper is Bickel et al. [2007], which relies upon a Restricted Eigenvalue (RE) assumption. The results of these works make it possible to estimate the parameter $\beta$ even in the so-called “$p$ much larger than $n$” regime (in our notation, the number of predictor variables $p$ corresponds to $MT$).

In this paper, we assume that the vectors $\beta_1^*, \ldots, \beta_T^*$ are not only sparse but also have the same sparsity pattern. This means that the set of indices which correspond to non zero components of $\beta_t^*$ is the same for every $t = 1, \ldots, T$. In other words, the response variable associated with each equation in (1.1) depends only on a small subset (of size $s \ll M$) of the corresponding predictor variables and the set of relevant predictors is preserved across the different equations. This assumption, that we further refer to as structured sparsity assumption, is motivated by some recent work on multi-task learning Argyriou et al. [2008]. It naturally leads to an extension of the Lasso method, the so-called group Lasso Yuan and Lin [2006], in which the error term is the average residual error across the different equations and the penalty term is a mixed $(2, 1)$-norm. The structured sparsity assumption induces a relation between the responses and, as we shall see, can be used to improve estimation.

The paper is organized as follows. In Section 2 we define the estimation method and comment on previous related work. In Section 3 we study the oracle properties of this estimator when the errors $W_t$ are Gaussian. Our main results concern upper bounds on the prediction error and the distance between the estimator and the true regression vector $\beta^*$. Specifically, Theorem 3.1 establishes that under the above structured sparsity assumption on $\beta^*$, the prediction error is essentially of the order of $s/n$. In particular, in the multi-task learning scenario, in which $T$ can grow, we are able to remove completely the effect of the number of predictor variables in the bounds. Next, in Section 4 under a stronger condition on the design matrices, we describe a simple modification of our method and show that it selects the correct sparsity pattern with an overwhelming probability (Theorem 4.1). We also find the rates of convergence of the estimators for mixed $(2, 1)$-norms with $1 \leq p \leq \infty$ (Theorem 4.2). The techniques of proofs build upon and extend those of Bickel et al. [2007] and Lounici [2008]. Finally, in Section 5 we discuss how our results can be extended to more general noise distributions, of which we only require the variance to be finite.

2 Method and related work

In this section we first introduce some notation and then describe the estimation method which we analyze in the paper. As stated above, our goal is to estimate $T$ linear regression functions identified by the parameters $\beta_1^*, \ldots, \beta_T^* \in \mathbb{R}^M$. We may write the model (1.1) in compact notation as

$$y = X \beta^* + W$$

(2.1)

where $y$ and $W$ are the $nT$-dimensional random vectors formed by stacking the vectors $y_1, \ldots, y_T$ and the vectors $W_1, \ldots, W_T$, respectively. Likewise $\beta^*$ denotes the vector obtained by stacking the regression parameter vectors $\beta_1^*, \ldots, \beta_T^*$. Unless otherwise specified, all vectors are meant to be column vectors. Thus, for every $t \in \mathbb{N}_T$, we write $y_t = (y_{ti} : i \in \mathbb{N}_n)^\top$ and $W_t = (W_{ti} : i \in \mathbb{N}_n)^\top$, where, hereafter, for every positive integer $k$, we let $\mathbb{N}_k$ be the set of integers from 1 and up to $k$. The $nT \times MT$ block diagonal design matrix $X$ has its $t$-th block
formed by the $n \times M$ matrix $X_t$. We let $x_{ti1}^T, \ldots, x_{tin}^T$ be the row vectors forming $X_t$ and $(x_{tj})_j$ the $j$-th component of the vector $x_{ti}$. Throughout the paper we assume that $x_{ti}$ are deterministic.

For every $\beta \in \mathbb{R}^{MT}$ we introduce $(\beta)^j \equiv \beta^j = (\beta_{tj} : t \in \mathbb{N}_T)^T$, that is, the vector formed by the coefficients corresponding to the $j$-th variable. For every $1 \leq p < \infty$ we define the mixed $(2, p)$-norm of $\beta$ as

$$
\|\beta\|_{2,p} = \left( \sum_{j=1}^M \left( \sum_{t=1}^T \beta_{tj}^2 \right)^{\frac{p}{2}} \right)^{\frac{1}{p}} = \left( \sum_{j=1}^M \|\beta^j\|^p \right)^{\frac{1}{p}}
$$

and the $(2, \infty)$-norm of $\beta$ as

$$
\|\beta\|_{2,\infty} = \max_{1 \leq j \leq M} \|\beta^j\|,
$$

where $\| \cdot \|$ is the standard Euclidean norm.

If $J \subseteq \mathbb{N}_M$ we let $\beta_J \in \mathbb{R}^{MT}$ be the vector formed by stacking the vectors $(\beta^j I\{j \in J\} : j \in \mathbb{N}_M)$, where $I\{\cdot\}$ denotes the indicator function. Finally we set $J(\beta) = \{j : \beta^j \neq 0, j \in \mathbb{N}_M\}$ and $M(\beta) = |J(\beta)|$ where $|J|$ denotes the cardinality of set $J \subset \{1, \ldots, M\}$. The set $J(\beta)$ contains the indices of the relevant variables shared by the vectors $\beta_1, \ldots, \beta_T$ and the number $M(\beta)$ quantifies the level of structured sparsity across those vectors.

We have now accumulated the sufficient information to introduce the estimation method. We define the empirical residual error

$$
\hat{S}(\beta) = \frac{1}{nT} \sum_{t=1}^T \sum_{i=1}^n (x_{ti}^T \beta_t - y_{ti})^2 = \frac{1}{nT} \|X \beta - y\|^2
$$

and, for every $\lambda > 0$, we let our estimator $\hat{\beta}$ be a solution of the optimization problem Argyriou et al. [2008]

$$
\min_{\beta} \hat{S}(\beta) + 2\lambda \|\beta\|_{2,1}. \tag{2.2}
$$

In order to study the statistical properties of this estimator, it is useful to derive the optimality condition for a solution of the problem (2.2). Since the objective function in (2.2) is convex, $\hat{\beta}$ is a solution of (2.2) if and only if $0$ (the $MT$-dimensional zero vector) belongs to the subdifferential of the objective function. In turn, this condition is equivalent to the requirement that

$$
-\nabla \hat{S}(\hat{\beta}) \in 2\lambda \partial \left( \sum_{j=1}^M \|\beta^j\| \right),
$$

where $\partial$ denotes the subdifferential (see, for example, Borwein and Lewis [2006] for more information on convex analysis). Note that

$$
\partial \left( \sum_{j=1}^M \|\beta^j\| \right) = \left\{ \theta \in \mathbb{R}^{MT} : \theta^j = \frac{\beta^j}{\|\beta^j\|} \text{ if } \beta^j \neq 0, \right. \\
\left. \quad \|\theta^j\| \leq 1, \text{ if } \beta^j = 0, j \in \mathbb{N}_M \right\}.
$$
Thus, $\hat{\beta}$ is a solution of (2.2) if and only if
\[
\frac{1}{nT}(X^\top(y - X\hat{\beta}))^j = \lambda \frac{\hat{\beta}_j}{\|\hat{\beta}_j\|}, \quad \text{if } \hat{\beta}_j \neq 0
\]
\[
\frac{1}{nT}\|X^\top(y - X\hat{\beta})\| \leq \lambda, \quad \text{if } \hat{\beta}_j = 0.
\]

Finally, let us comment on previous related work. Our estimator is a special case of the group Lasso estimator [Yuan and Lin 2006]. Several papers analyzing statistical properties of the group Lasso appeared quite recently [Bach 2008], [Chesneau and Hebiri 2007], [Huang et al. 2008], [Koltchinskii and Yu 2008], [Meier et al. 2006, 2008], [Nardi and Rinaldo 2008], [Ravikumar et al. 2007]. Most of them are focused on the group Lasso for additive models [Huang et al. 2008], [Koltchinskii and Yu 2008], [Meier et al. 2008], [Ravikumar et al. 2007] or generalized linear models [Meier et al. 2008]. Special choice of groups is studied in [Chesneau and Hebiri 2007]. Discussion of the group Lasso in a relatively general setting is given by [Bach 2008] and [Nardi and Rinaldo 2008]. Bach [2008] assumes that the predictors $x_{ti}$ are random with a positive definite covariance matrix and proves results on consistent selection of sparsity pattern $J(\beta^*)$ when the dimension of the model ($p = MT$ in our case) is fixed and $n \to \infty$. Nardi and Rinaldo [2008] consider a setting that covers ours and address the issue of sparsity oracle inequalities in the spirit of [Bickel et al. 2007]. However, their bounds are too coarse (see comments in Section 3 below). Obozinski et al. [2008] replace in (2.2) the $(2, 1)$-norms by $(q, 1)$-norms with $q > 1$ and show that the resulting estimator achieves consistent selection of the sparsity pattern under the assumption that all the rows of matrices $X_t$ are independent Gaussian random vectors with the same covariance matrix.

This literature does not demonstrate theoretical advantages of the group Lasso as compared to the usual Lasso. One of the aims of this paper is to show that such advantages do exist in the multi-task learning setup. In particular, our Theorem 3.1 implies that the prediction bound for the group Lasso estimator that we use here is by at least a factor of $T$ better than for the standard Lasso under the same assumptions. Furthermore, we demonstrate that as the number of tasks $T$ increases the dependence of the bound on $M$ disappears, provided that $M$ grows at the rate slower than $\exp(\sqrt{T})$.

### 3 Sparsity oracle inequality

Let $1 \leq s \leq M$ be an integer that gives an upper bound on the structured sparsity $M(\beta^*)$ of the true regression vector $\beta^*$. We make the following assumption.

**Assumption 3.1.** There exists a positive number $\kappa = \kappa(s)$ such that
\[
\min \left\{ \frac{\sqrt{\Delta^\top X^\top X \Delta}}{\sqrt{n}\|\Delta_J\|} : |J| \leq s, \Delta \in \mathbb{R}^{MT} \setminus \{0\}, \quad \|\Delta_{J^c}\|_{2,1} \leq 3\|\Delta_J\|_{2,1} \right\} \geq \kappa,
\]
where $J^c$ denotes the complement of the set of indices $J$. 

To emphasize the dependency of Assumption 3.1 on $s$, we will sometimes refer to it as Assumption RE($s$). This is a natural extension to our setting of the Restricted Eigenvalue assumption for the usual Lasso and Dantzig selector from Bickel et al. [2007]. The $\ell_1$ norms are now replaced by the mixed (2,1)-norms. Note that, however, the analogy is not complete. In fact, the sample size $n$ in the usual Lasso setting corresponds to $nT$ in our case, whereas in Assumption 3.1 we consider $\sqrt{\Delta^\top X^\top X \Delta / n}$ and not $\sqrt{\Delta^\top X^\top X \Delta / (nT)}$. This is done in order to have a correct normalization of $\kappa$ without compulsory dependence on $T$ (if we use the term $\sqrt{\Delta^\top X^\top X \Delta / (nT)}$ in Assumption 3.1, then $\kappa \sim T^{-1/2}$ even in the case of the identity matrix $X^\top X/n$).

Several simple sufficient conditions for Assumption 3.1 with $T = 1$ are given in Bickel et al. [2007]. Similar sufficient conditions can be stated in our more general setting. For example, it is enough to suppose that each of the matrices $X^\top t X_t/n$ is positive definite or satisfies a Restricted Isometry condition as in Cand`es and Tao [2005] or the coherence condition (cf. Lemma 4.1 below).

**Lemma 3.1.** Consider the model (1.1) for $M \geq 2$ and $T, n \geq 1$. Assume that the random vectors $W_1, \ldots, W_T$ are i.i.d. Gaussian with zero mean and covariance matrix $\sigma^2 I_{n \times n}$, all diagonal elements of the matrix $X^\top X/n$ are equal to 1 and $M(\beta^*) \leq s$. Let

$$\lambda = \frac{2\sigma}{\sqrt{nT}} \left( 1 + \frac{A \log M}{\sqrt{T}} \right)^{1/2},$$

where $A > 8$ and let $q = \min(8 \log M, A\sqrt{T}/8)$. Then with probability at least $1 - M^{1-q}$, for any solution $\hat{\beta}$ of problem (2.2) and all $\beta \in \mathbb{R}^{MT}$ we have

$$\frac{1}{nT} \|X(\hat{\beta} - \beta^*)\|^2 + \lambda \|\hat{\beta} - \beta\|_{2,1} \leq$$

$$\leq \frac{1}{nT} \|X(\beta - \beta^*)\|^2 + 4\lambda \sum_{j \in J(\beta)} \|\hat{\beta}^j - \beta^j\|, \quad (3.1)$$

$$\frac{1}{nT} \max_{1 \leq j \leq M} \|X^\top X(\beta^* - \hat{\beta})^j\| \leq \frac{3}{2} \lambda, \quad (3.2)$$

$$M(\hat{\beta}) \leq \frac{4\phi_{\max}}{\lambda^2 nT^2} \|X(\hat{\beta} - \beta^*)\|^2, \quad (3.3)$$

where $\phi_{\max}$ is the maximum eigenvalue of the matrix $X^\top X/n$.

**Proof.** For all $\beta \in \mathbb{R}^{MT}$, we have

$$\frac{1}{nT} \|X\hat{\beta} - y\|^2 + 2\lambda \sum_{j=1}^M \|\hat{\beta}^j\| \leq \frac{1}{nT} \|X\beta - y\|^2 + 2\lambda \sum_{j=1}^M \|\beta^j\|$$

which, using $y = X\beta^* + W$, is equivalent to

$$\frac{1}{nT} \|X(\hat{\beta} - \beta^*)\|^2 \leq \frac{1}{nT} \|X(\beta - \beta^*)\|^2$$

$$+ \frac{2}{nT} W^\top X(\hat{\beta} - \beta) + 2\lambda \sum_{j=1}^M (\|\beta^j\| - \|\hat{\beta}^j\|). \quad (3.4)$$
By Hölder’s inequality, we have that

$$W^\top X (\hat{\beta} - \beta) \leq \|X^\top W\|_{2,\infty} \|\hat{\beta} - \beta\|_{2,1}$$

where

$$\|X^\top W\|_{2,\infty} = \max_{1 \leq j \leq M} \left( \sum_{t=1}^{T} \left( \sum_{i=1}^{n} (x_{ti})_j W_{ti} \right)^2 \right)^{1\over 2}.$$ 

Consider the random event

$$A = \left\{ \frac{1}{nT} \|X^\top W\|_{2,\infty} \leq \frac{\lambda}{2} \right\}.$$ 

Since we assume all diagonal elements of the matrix $X^\top X/n$ to be equal to 1, the random variables

$$V_{ij} = \frac{1}{\sigma \sqrt{n}} \sum_{i=1}^{n} (x_{ti})_j W_{ti},$$ 

t = 1, \ldots, T, \text{ are i.i.d. standard Gaussian. Using this fact we can write, for any } j = 1, \ldots, M,$$

$$\Pr \left( \sum_{t=1}^{T} \left( \sum_{i=1}^{n} (x_{ti})_j W_{ti} \right)^2 \geq \frac{\lambda^2 (nT)^2}{4} \right)$$

$$= \Pr \left( \chi_T^2 \geq \frac{\lambda^2 n T^2}{4 \sigma^2} \right)$$

$$= \Pr \left( \chi_T^2 \geq T + A \sqrt{T \log M} \right),$$

where $\chi_T^2$ is a chi-square random variable with $T$ degrees of freedom. We now apply Lemma A.1, the union bound and the fact that $A > 8$ to get

$$\Pr(A^c) \leq M \exp \left( -{\frac{A \log M}{8}} \min \left( \sqrt{T}, A \log M \right) \right) \leq M^{1-q}.$$ 

It follows from (3.4) that, on the event $A$,

$$\frac{1}{nT} \|X(\hat{\beta} - \beta^*)\|^2 + \lambda \sum_{j=1}^{M} \|\hat{\beta}^j - \beta^j\| \leq$$

$$\frac{1}{nT} \|X(\beta - \beta^*)\|^2 + 2 \lambda \sum_{j=1}^{M} \left( \|\hat{\beta}^j - \beta^j\| + \|\beta^j\| - \|\hat{\beta}^j\| \right)$$

$$\leq \frac{1}{nT} \|X(\beta - \beta^*)\|^2 + 4 \lambda \sum_{j \in J(\beta)} \|\hat{\beta}^j - \beta^j\|,$$
which coincides with (3.1). To prove (3.2), we use the inequality

\[
\frac{1}{nT} \max_{1 \leq j \leq M} \| (X^T (y - X \hat{\beta}))^j \| \leq \lambda, \tag{3.5}
\]

which follows from (2.3) and (2.4). Then,

\[
\frac{1}{nT} \| (X^T (X (\hat{\beta} - \beta^*))^j \| \leq \frac{1}{nT} \| (X^T (X \hat{\beta} - y))^j \| + \frac{1}{nT} \| (X^T W)^j \|,
\]

where we have used \( y = X \beta^* + W \) and the triangle inequality. The result then follows by combining the last inequality with inequality (3.5) and using the definition of the event \( A \).

Finally, we prove (3.3). First, observe that, on the event \( A \),

\[
\frac{1}{nT} \| (X^T X (\hat{\beta} - \beta^*))^j \| \geq \frac{\lambda}{2}, \quad \text{if } \hat{\beta}^j \neq 0.
\]

This fact follows from (2.3), (2.1) and the definition of the event \( A \). The following chain yields the result:

\[
M(\hat{\beta}) \leq \frac{4}{\lambda^2 (nT)^2} \sum_{j \in J(\hat{\beta})} \| (X^T X (\hat{\beta} - \beta^*))^j \|^2 \\
\leq \frac{4}{\lambda^2 (nT)^2} \sum_{j=1}^{M} \| (X^T X (\hat{\beta} - \beta^*))^j \|^2 \\
= \frac{4}{\lambda^2 (nT)^2} \| X^T X (\hat{\beta} - \beta^*) \|^2 \\
\leq \frac{4\phi_{\text{max}}}{\lambda^2 nT^2} \| X (\hat{\beta} - \beta^*) \|^2.
\]

We are now ready to state the main result of this section.

**Theorem 3.1.** Consider the model (1.1) for \( M \geq 2 \) and \( T, n \geq 1 \). Assume that the random vectors \( W_1, \ldots, W_T \) are i.i.d. Gaussian with zero mean and covariance matrix \( \sigma^2 I_{n \times n} \), all diagonal elements of the matrix \( X^T X/n \) are equal to 1 and \( M(\beta^*) \leq s \). Furthermore let Assumption 3.1 hold with \( \kappa = \kappa(s) \) and let \( \phi_{\text{max}} \) be the largest eigenvalue of the matrix \( X^T X/n \). Let

\[
\lambda = \frac{2\sigma}{\sqrt{nT}} \left( 1 + \frac{A \log M}{\sqrt{T}} \right)^{1/2},
\]

where \( A > 8 \) and let \( q = \min(8 \log M, A\sqrt{T}/8) \). Then with probability at least \( 1 - M^{-1-q} \), for
any solution \( \hat{\beta} \) of problem (2.2) we have

\[
\frac{1}{nT} \| X(\hat{\beta} - \beta^*) \|^2 \leq \frac{64 \sigma^2 s}{\kappa^2} \left( 1 + \frac{A \log M}{\sqrt{T}} \right)
\]

\[
\frac{1}{\sqrt{T}} \| \hat{\beta} - \beta^* \|_{2,1} \leq \frac{32 \sigma \sqrt{s}}{\kappa^2 \sqrt{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}}
\]

\[
M(\hat{\beta}) \leq \frac{64 \phi_{\text{max}}}{\kappa^2}.
\]

If, in addition, Assumption RE(2s) holds, then with the same probability for any solution \( \hat{\beta} \) of problem (2.2) we have

\[
\frac{1}{\sqrt{T}} \| \hat{\beta} - \beta^* \| \leq \frac{8 \sqrt{10} \sigma}{\kappa^2 (2s)} \sqrt{\frac{s}{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}}.
\]

**Proof.** We act similarly to the proof of Theorem 6.2 in Bickel et al. [2007]. Let \( J = J(\beta^*) = \{ j : (\beta^*)_j \neq 0 \} \). By inequality (3.1) with \( \beta = \beta^* \) we have, on the even \( A \), that

\[
\frac{1}{nT} \| X(\hat{\beta} - \beta^*) \|^2 \leq 4 \lambda \sum_{j \in J} \| \hat{\beta}_j - \beta_*^j \|
\]

\[
\leq 4 \lambda \sqrt{s} \| (\hat{\beta} - \beta^*)_J \|.
\]

Moreover by the same inequality, on the event \( A \), we have \( \sum_{j=1}^{M} \| \hat{\beta}_j^i - \beta_*^j \| \leq 4 \sum_{j \in J} \| \hat{\beta}_j - \beta_*^j \| \), which implies that \( \sum_{j \in J^c} \| \hat{\beta}_j - \beta_*^j \| \leq 3 \sum_{j \in J} \| \hat{\beta}_j - \beta_*^j \| \). Thus, by Assumption 3.1

\[
\| (\hat{\beta} - \beta^*)_J \| \leq \frac{\| X(\hat{\beta} - \beta^*) \|}{\kappa \sqrt{n}}.
\]  

(3.11)

Now, (3.6) follows from (3.10) and (3.11). Inequality (3.7) follows again by noting that

\[
\sum_{j=1}^{M} \| \hat{\beta}_j - \beta_*^j \| \leq 4 \sum_{j \in J} \| \hat{\beta}_j - \beta_*^j \| \leq 4 \sqrt{s} \| (\hat{\beta} - \beta^*)_J \|
\]

and then using (3.6). Inequality (3.8) follows from (3.3) and (3.6).

Finally, we prove (3.9). Let \( \Delta = \hat{\beta} - \beta^* \) and let \( J' \) be the set of indices in \( J^c \) corresponding to \( s \) maximal in absolute value norms \( \| \Delta_j^i \| \). Consider the set \( J_{2s} = J \cup J' \). Note that \( |J_{2s}| = 2s \). Let \( \| \Delta_{(k)}^{(j)} \| \) denote the \( k \)-th largest norm in the set \( \{ \| \Delta_j^i \| : j \in J^c \} \). Then, clearly,

\[
\| \Delta_{(k)}^{(j)} \| \leq \sum_{j \in J^c} \| \Delta_j^i \| / k = \| \Delta_{J^c} \|_{2,1} / k.
\]
This and the fact that $\|\Delta_{J^c}\|_{2,1} \leq 3\|\Delta_J\|_{2,1}$ on the event $\mathcal{A}$ implies

$$\sum_{j \in J_{2s}} \|\Delta_j\|^2 \leq \sum_{k = s+1}^{\infty} \frac{\|\Delta_{J^c}\|_{2,1}^2}{k^2} \leq \frac{\|\Delta_{J^c}\|_{2,1}^2}{s} \leq 9 \frac{\|\Delta_J\|_{2,1}^2}{s} \leq 9 \sum_{j \in J} \|\Delta_j\|^2 \leq 9 \sum_{j \in J_{2s}} \|\Delta_j\|^2.$$ 

Therefore, on $\mathcal{A}$ we have

$$\|\Delta\|^2 \leq 10 \sum_{j \in J_{2s}} \|\Delta_j\|^2 \equiv 10\|\Delta_{J_{2s}}\|^2$$

and also from (3.10):

$$\frac{1}{nT} \|X\Delta\|^2 \leq 4\lambda \sqrt{s} \|\Delta_{J_{2s}}\|.$$ 

In addition, $\|\Delta_{J^c}\|_{2,1} \leq 3\|\Delta_J\|_{2,1}$ easily implies that

$$\|\Delta_{J_{2s}}\|_{2,1} \leq 3\|\Delta_{J_{2s}}\|_{2,1}.$$ 

Combining these facts and (3.13) with Assumption RE(2s) we find that on the event $\mathcal{A}$ the following holds:

$$\|\Delta_{J_{2s}}\| \leq \frac{4\lambda \sqrt{s} T}{\kappa^2 (2s)}.$$ 

This inequality and (3.12) yield (3.9).

Theorem 3.1 is valid for any fixed $n, M, T$; the approach is non-asymptotic. Some relations between these parameters are relevant in the particular applications and various asymptotics can be derived as corollaries. For example, in multi-task learning it is natural to assume that $T \geq n$, and the motivation for our approach is the strongest if also $M \gg n$. The bounds of Theorem 3.1 are meaningful if the sparsity index $s$ is small as compared to the sample size $n$ and the logarithm of the dimension $\log M$ is not too large as compared to $\sqrt{T}$.

Note also that the values $T$ and $\sqrt{T}$ in the denominators of the right-hand sides of (3.6), (3.7), and (3.9) appear quite naturally. For instance, the norm $\|\hat{\beta} - \beta^*\|_{2,1}$ in (3.7) is a sum of $M$ terms each of which is a Euclidean norm of a vector in $\mathbb{R}^T$, and thus it is of the order $\sqrt{T}$ if all the components are equal. Therefore, (3.7) can be interpreted as a correctly normalized “error per coefficient” bound.

Several important conclusions can be drawn from Theorem 3.1.

1. The dependence on the dimension $M$ is negligible for large $T$. Indeed, the bounds of Theorem 3.1 become independent of $M$ if we choose the number of tasks $T$ larger than $\log^2 M$. A striking fact is that no relation between the sample size $n$ and the dimension $M$ is required. This is quite in contrast to the previous results on sparse recovery where
the assumption \( \log M = o(n) \) was considered as \textit{sine qua non} constraint. For example, Theorem 3.1 gives meaningful bounds if \( M = \exp(n^\gamma) \) for arbitrarily large \( \gamma > 0 \), provided that \( T > n^{2\gamma} \). This is due to the structured sparsity assumption that we naturally exploit in the multi-task scenario.

2. \textbf{Our estimator is better than the standard Lasso in the multi-task setup.} Theorem 3.1 witnesses that our group Lasso estimator admits substantially better error bounds than the usual Lasso. Let us explain this considering the example of the prediction error bound (3.9). Indeed, for the same multi-task setup, we can apply a usual Lasso estimator \( \hat{\beta}^L \), that is a solution of the following optimization problem

\[
\min_{\beta} S(\beta) + 2\lambda \sum_{t=1}^T \sum_{j=1}^M |\beta_{tj}|
\]

Assume, for instance, that we are in the most favorable situation where \( M < n \), each of the matrices \( \frac{1}{n}X_t^T X_t \) is positive definite and has minimal eigenvalue greater than \( \kappa^2 \) (this, of course, implies Assumption 3.1). We can then apply inequality (7.8) from Bickel et al. [2007] with

\[
\lambda = A\sigma \sqrt{\frac{\log(MT)}{nT}}
\]

where \( A > 2\sqrt{2} \), to obtain that, with probability at least \( 1 - (MT)^{-\frac{A^2}{8}} \), it holds

\[
\frac{1}{nT}||X(\hat{\beta}^L - \beta^*)||^2 \leq \frac{16A^2}{\kappa^2\sigma^2 sT \log(MT)}.
\]

Indeed, when applying (7.8) of Bickel et al. [2007] we account for the fact that the parameters \( n, M, s \) therein correspond to \( nT, MT, sT \) in our setup, and the minimal eigenvalue of the matrix \( \frac{1}{nT}X^T X \) is greater than \( \kappa^2/T \). Comparison with (3.9) leads to the conclusion that the prediction bound for our estimator is by at least a factor of \( T \) better than for the standard Lasso under the same assumptions. Let us emphasize that the improvement is due to the property that \( \beta^* \) is structured sparse. The second inherent property of our setting, that is, the fact that the matrix \( X^T X \) is block-diagonal, can be characterized as important but not indispensable. We discuss this in the next remark.

3. \textbf{Theorem 3.1 applies to the general group Lasso setting.} Indeed, the proofs in this section do not use the fact that the matrix \( X^T X \) is block-diagonal. The only restriction on \( X^T X \) is given in Assumption 3.1. For example, Assumption 3.1 is obviously satisfied if \( \frac{1}{nT}X^T X/(nT) \) (the correctly normalized Gram matrix of the regression model (2.1)) has a positive minimal eigenvalue. However, the price for having this property (or Assumption 3.1 in general), as well as the resulting error bounds, can be different for the block-diagonal (multi-task) setting and the full matrix \( X \) setting.

Finally, we note that Nardi and Rinaldo [2008] follow the scheme of the proof of Bickel et al. [2007] to derive similar in spirit to ours but coarse oracle inequalities. Their results do not explain the advantages discussed in the points 1–3 above. Indeed, the tuning parameter \( \lambda \) chosen
in [Nardi and Rinaldo (2008), pp. 614–615], is larger than our $\lambda$ by at least a factor of $\sqrt{T}$. As a consequence, the corresponding bounds in the oracle inequalities of [Nardi and Rinaldo (2008)] are larger than ours by positive powers of $T$.

4 Coordinate-wise estimation and selection of sparsity pattern

In this section, we show how from any solution of the problem (2.2) we can reliably estimate the correct sparsity pattern with high probability.

We first introduce some more notation. We define the Gram matrix of the design $\Psi = \frac{1}{n} X^\top X$. Note that $\Psi$ is a $MT \times MT$ block-diagonal matrix with $T$ blocks of dimension $M \times M$ each. We denote these blocks by $\Psi_t = \frac{1}{n} X_t^\top X_t \equiv (\Psi_{tj,tk})_{j,k=1,...,M}$.

In this section we assume that the following condition holds true.

Assumption 4.1. The elements $\Psi_{tj,tk}$ of the Gram matrix $\Psi$ satisfy

$$\Psi_{tj,tj} = 1, \quad \forall 1 \leq j \leq M, 1 \leq t \leq T,$$

and

$$\max_{1 \leq t \leq T, j \neq k} |\Psi_{tj,tk}| \leq \frac{1}{\sqrt{T}} \frac{1}{\alpha s},$$

for some integer $s \geq 1$ and some constant $\alpha > 1$.

Note that the above assumption on $\Psi$ implies Assumption 3.1 as we prove in the following lemma.

Lemma 4.1. Let Assumption 4.1 be satisfied. Then Assumption 3.1 is satisfied with $\kappa = \sqrt{1 - \frac{1}{\alpha}}$.

Proof. For any subset $J$ of $\{1, \ldots, M\}$ such that $|J| \leq s$ and any $\Delta \in \mathbb{R}^{MT}$ such that $\|\Delta_{J^c}\|_{2,1} \leq 3 \|\Delta_{J}\|_{2,1}$, we have

$$\frac{\Delta_J^\top \Psi \Delta_J}{\|\Delta_J\|^2} = 1 + \frac{\Delta_J^\top (\Psi - I_{MT \times MT}) \Delta_J}{\|\Delta_J\|^2} \geq 1 - \frac{1}{\sqrt{T} \alpha s} \frac{\left( \sum_{j \in J} \sum_{t=1}^T |\Delta_{jt}| \right)^2}{\|\Delta_J\|^2} \geq 1 - \frac{1}{\sqrt{T} \alpha},$$

where we have used Assumption 4.1 and the Cauchy-Schwarz inequality. Next, using consecutively Assumption 4.1 the Cauchy-Schwarz inequality and the inequality $\|\Delta_{J^c}\|_{2,1} \leq 3 \|\Delta_{J}\|_{2,1}$.
we obtain
\[
\frac{|\Delta_j^\top \Psi \Delta_j|}{\|\Delta_j\|^2} \leq \frac{1}{7\alpha s} \sum_{t=1}^T \sum_{j \in J} \sum_{k \in Jc} |\Delta_{tj}| |\Delta_{tk}|
\leq \frac{1}{7\alpha s} \sum_{j \in J, k \in Jc} \|\Delta_j\| \|\Delta_k\|
\leq \frac{3}{7\alpha s} \|\Delta_j\|_{2,1}
\leq \frac{3}{7\alpha}.
\]

Combining these inequalities we find
\[
\Delta^\top \Psi \Delta \geq \frac{\Delta^\top_j \Psi \Delta_j}{\|\Delta_j\|^2} + \frac{2\Delta^\top_j \Psi \Delta_j}{\|\Delta_j\|^2} \geq 1 - \frac{1}{\alpha} > 0.
\]

Note also that, by an argument as in [Lounici, 2008], it is not hard to show that under Assumption 4.1 the vector $\beta^*$ satisfying (2.1) is unique.

Theorem 4.1 provides bounds for compound measures of risk, that is, depending simultaneously on all the vectors $\beta_j$. An important question is to evaluate the performance of estimators for each of the components $\beta_j$ separately. The next theorem provides a bound of this type and, as a consequence, a result on the selection of sparsity pattern.

**Theorem 4.1.** Consider the model (1.1) for $M \geq 2$ and $T, n \geq 1$. Let the assumptions of Lemma 3.1 be satisfied and let Assumption 4.1 hold with the same $s$. Set
\[
c = \left(3 + \frac{32}{7(\alpha - 1)}\right) \sigma.
\]

Let $\lambda, A$ and $W_1, \ldots, W_T$ be as in Lemma 3.1. Then with probability at least $1 - M^{1-q}$, where $q = \min(8 \log M, A \sqrt{T}/8)$, for any solution $\hat{\beta}$ of problem (2.2) we have
\[
\frac{1}{\sqrt{T}} \|\hat{\beta} - \beta^*\|_{2,\infty} \leq \frac{c}{\sqrt{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}}.
\]

If, in addition,
\[
\min_{j \in J(\beta^*)} \frac{1}{\sqrt{T}} \|(\beta^*)_j\|^2 > \frac{2c}{\sqrt{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}},
\]
then with the same probability for any solution $\hat{\beta}$ of problem (2.2) the set of indices
\[
\hat{J} = \left\{ j : \frac{1}{\sqrt{T}} \|\hat{\beta}_j\|^2 > \frac{c}{\sqrt{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}} \right\}
\]
estimates correctly the sparsity pattern $J(\beta^*)$, that is,
\[
\hat{J} = J(\beta^*).
Proof. Set $\Delta = \hat{\beta} - \beta^*$. Using Assumption 4.1, we obtain
\[
\|\Delta\|_{2,\infty} \leq \|\Psi\Delta\|_{2,\infty} + \|(\Psi - I_{MT\times MT})\Delta\|_{2,\infty}
\]
\[
\leq \|\Psi\Delta\|_{2,\infty} + \max_{1 \leq j \leq M} \left( \sum_{t=1}^{T} \left| \sum_{k=1, k \neq j}^{M} \Psi_{tj,tk} \Delta_{tk} \right| \right)
\]
\[
\leq \|\Psi\Delta\|_{2,\infty} + \sum_{k=1, k \neq j}^{M} \|\Delta^k\| \left( \sum_{t=1}^{T} \max_{j \neq k} |\Psi_{tj,tk}|^2 \right)^{1/2}
\]
\[
\leq \|\Psi\Delta\|_{2,\infty} + \frac{\|\Delta\|_{2,\infty} \sqrt{T}}{7\alpha s}.
\]
Thus, by Lemma 3.1 and Theorem 3.1, with probability at least $1 - M^{1-q}$,
\[
\|\Delta\|_{2,\infty} \leq \left( \frac{3}{2} + \frac{16}{7\alpha s} \right) \lambda T.
\]
By Lemma 4.1, $\alpha \kappa^2 = \alpha - 1$, which yields the first result of the theorem. The second result follows from the first one in an obvious way.

Assumption of type (4.1) is inevitable in the context of selection of sparsity pattern. It says that the vectors $(\beta^*)^j$ cannot be arbitrarily close to 0 for $j$ in the pattern. Their norms should be at least somewhat larger than the noise level.

The second result of Theorem 4.1 (selection of sparsity pattern) can be compared with Bach [2008], Nardi and Rinaldo [2008] who considered the Group Lasso. There are several differences. First, our estimator $\hat{J}$ is based on thresholding of the norms $\|\hat{\beta}^j\|$, while Bach [2008], Nardi and Rinaldo [2008] take instead the set where these norms do not vanish. In practice, the latter is known to be a poor selector; it typically overestimates the true sparsity pattern. Second, Bach [2008], Nardi and Rinaldo [2008] consider specific asymptotic settings, while our result holds for any fixed $n, M, T$. Different kinds of asymptotics can be therefore obtained as simple corollaries. Finally, note that the estimator $\hat{\beta}$ is not necessarily unique. Though Nardi and Rinaldo [2008] does not discuss this fact, the proof there only shows that there exists a subsequence of solutions $\hat{\beta}$ of (2.2) such that the set $\{j : \|\hat{\beta}^j\| \neq 0\}$ coincides with the sparsity pattern $J(\beta^*)$ in some specified asymptotics (we note here the “if and only if” claim before formula (23) in Nardi and Rinaldo [2008] is not proved). In contrast, the argument in Theorem 4.1 does not require any analysis of the uniqueness issues, though it is not excluded that the solution is indeed unique. It guarantees that simultaneously for all solutions $\hat{\beta}$ of (2.2) and any fixed $n, M, T$ the correct selection is done with high probability.

Theorems 3.3 and 4.1 imply the following corollary.

Corollary 4.1. Consider the model (1.1) for $M \geq 2$ and $T, n \geq 1$. Let the assumptions of Lemma 3.1 be satisfied and let Assumption 4.1 holds with the same $s$. Let $\lambda, A$ and $W_1, \ldots, W_T$
be as in Lemma 3.1. Then with probability at least \(1 - M^{-q}\), where \(q = \min(8 \log M, A \sqrt{T}/8)\), for any solution \(\hat{\beta}\) of problem (2.2) and any \(1 \leq p < \infty\) we have

\[
\frac{1}{\sqrt{T}} \|\hat{\beta} - \beta^*\|_{2,p} \leq c_1 \sigma \frac{s^{1/p}}{\sqrt{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}} ,
\]

where

\[
c_1 = \left( \frac{32 \alpha}{\alpha - 1} \right)^{1/p} \left( 3 + \frac{32}{7(\alpha - 1)} \right)^{1-\frac{1}{p}} .
\]

If, in addition, (4.1) holds, then with the same probability for any solution \(\hat{\beta}\) of problem (2.2) and any \(1 \leq p < \infty\) we have

\[
\frac{1}{\sqrt{T}} \|\hat{\beta} - \beta^*\|_{2,p} \leq c_1 \sigma \frac{|\hat{J}|^{1/p}}{\sqrt{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}} ,
\]

where \(\hat{J}\) is defined in (4.1).

**Proof.** Set \(\Delta = \hat{\beta} - \beta\). For any \(p \geq 1\) we have

\[
\frac{1}{\sqrt{T}} \|\Delta\|_{2,p} \leq \left( \frac{1}{\sqrt{T}} \|\Delta\|_{2,1} \right)^{1/p} \left( \frac{1}{\sqrt{T}} \|\Delta\|_{2,\infty} \right)^{1-\frac{1}{p}} .
\]

Combining (3.7), (4.1) with \(\kappa = \sqrt{1 - \frac{1}{\alpha}}\) and the above display yields the first result. 

Inequalities (4.1) and (4.1) provide confidence intervals for the unknown parameter \(\beta^*\) in mixed \((2,p)\)-norms.

For averages of the coefficients \(\beta_{ij}\) we can establish a sign consistency result which is somewhat stronger than the result in Theorem 4.1. For any \(\beta \in \mathbb{R}^M\), define \(\text{sign}(\beta) = (\text{sign}(\beta^1), \ldots, \text{sign}(\beta^M))^\top\) where

\[
\text{sign}(t) = \begin{cases} 
1 & \text{if } t > 0, \\
0 & \text{if } t = 0, \\
-1 & \text{if } t < 0.
\end{cases}
\]

Introduce the averages

\[
a^*_j = \frac{1}{T} \sum_{t=1}^T \beta^*_{tj}, \quad \hat{a}_j = \frac{1}{T} \sum_{t=1}^T \hat{\beta}_{tj}.
\]

Consider the threshold \(\tau = \frac{\sigma}{\sqrt{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}}\) and define a thresholded estimator

\[
\tilde{a}_j = \hat{a}_j I\{|\hat{a}_j| > \tau\}.
\]

Let \(\tilde{a}\) and \(a^*\) be the vectors with components \(\tilde{a}_j\) and \(a^*_j\), \(j = 1, \ldots, M\), respectively. We need the following additional assumption.

14
Assumption 4.2. It holds:

$$\min_{j \in J(a^*)} |a_j^*| \geq \frac{2c}{\sqrt{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}}.$$  

This assumption says that we cannot recover arbitrarily small components. Similar assumptions are standard in the literature on sign consistency (see, for example, Lounici [2008] for more details and references).

Theorem 4.2. Consider the model (1.1) for $M \geq 2$ and $T, n \geq 1$. Let the assumptions of Lemma 3.1 be satisfied and let Assumption 4.1 hold with the same $s$. Let $\lambda$ and $A$ be defined as in Lemma 3.1 and $c$ as in Theorem 4.1. Then with probability at least $1 - M^{-q}$, where $q = \min(8 \log M, A \sqrt{T} / 8)$, for any solution $\hat{\beta}$ of problem (2.2) we have

$$\max_{1 \leq j \leq M} |\hat{a}_j - a_j^*| \leq \frac{c}{\sqrt{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}}.$$  

If, in addition, Assumption 4.2 holds, then with the same probability, for any solution $\hat{\beta}$ of problem (2.2), $\hat{a}$ recovers the sign pattern of $a^*$:

$$\vec{\text{sign}}(\hat{a}) = \vec{\text{sign}}(a^*).$$

Proof. Note that for every $j \in \mathbb{N}_M$

$$|\hat{a}_j - a_j^*| \leq \frac{1}{\sqrt{T}} \|\hat{\beta} - \beta^*\|_2, 1,2 \leq \frac{c}{\sqrt{n}} \sqrt{1 + \frac{A \log M}{\sqrt{T}}}.$$  

The proof is then similar to that of Theorem 4.1.

We may consider a stronger assumption that $\beta_t^* = a$ for every $t \in \mathbb{N}_T$, where $a = (a_j : j \in \mathbb{N}_M) \in \mathbb{R}^M$ is an unknown vector to be estimated. Then Theorem 4.2 implies that $\hat{a}$ is a $\sqrt{n}$-consistent (up to logarithms) estimator of all the components of $a$ and the sparsity (and sign) pattern of $a$ is correctly recovered by that of $\hat{a}$ with overwhelming probability.

5 Non-Gaussian noise

In this section, we only assume that the random variables $W_{ti}, i \in \mathbb{N}_n, t \in \mathbb{N}_T$, are independent with zero mean and finite variance $\mathbb{E}[W_{ti}^2] \leq \sigma^2$. In this case the results remain similar to those of the previous sections, though the concentration effect is weaker. We need the following technical assumption

Assumption 5.1. The matrix $X$ is such that

$$\frac{1}{nT} \sum_{t=1}^T \sum_{i=1}^n \max_{1 \leq j \leq M} |(x_{ti})_j|^2 \leq c',$$

for a constant $c' > 0$. 

This assumption is quite mild. It is satisfied for example, if all \((x_{it})_j\) are bounded in absolute value by a constant uniformly in \(i, t, j\). We have the two following theorems.

**Theorem 5.1.** Consider the model (1.1) for \(M \geq 3\) and \(T, n \geq 1\). Assume that the random vectors \(W_1, \ldots, W_T\) are independent with zero mean and finite variance \(\mathbb{E}[W_i^2] \leq \sigma^2\), all diagonal elements of the matrix \(X^\top X/n\) are equal to 1 and \(M(\beta^*) \leq s\). Let also Assumption 5.1 be satisfied. Furthermore let \(\kappa\) be defined as in Assumption 3.1 and \(\phi_{\text{max}}\) be the largest eigenvalue of the matrix \(X^\top X/n\). Let

\[
\lambda = \sigma \sqrt{\frac{(\log M)^{1+\delta}}{nT}}, \quad \delta > 0.
\]

Then with probability at least \(1 - \frac{(2e \log M - e)c'}{(\log M)^{1+\delta}}\), for any solution \(\hat{\beta}\) of problem (2.2) we have

\[
\frac{1}{nT} \|X(\hat{\beta} - \beta^*)\|^2 \leq \frac{16}{\kappa^2 s} \frac{(\log M)^{1+\delta}}{n},
\]

\[
\frac{1}{\sqrt{T}} \|\hat{\beta} - \beta^*\|_{2,1} \leq \frac{16}{\kappa^2 \sigma s} \sqrt{\frac{(\log M)^{1+\delta}}{n}},
\]

\[
M(\hat{\beta}) \leq \frac{64 \phi_{\text{max}}}{\kappa^2 s}.
\]

If, in addition, Assumption RE(2s) holds, then with the same probability for any solution \(\hat{\beta}\) of problem (2.2) we have

\[
\frac{1}{T} \|\hat{\beta} - \beta^*\|^2 \leq \frac{160}{\kappa^4 (2s)} \frac{\sigma^2 s (\log M)^{1+\delta}}{n}.
\]

**Theorem 5.2.** Consider the model (1.1) for \(M \geq 3\) and \(T, n \geq 1\). Let the assumptions of Theorem 5.1 be satisfied and let Assumption 4.1 hold with the same \(s\). Set

\[
c = \left(\frac{3}{2} + \frac{1}{7(\alpha - 1)}\right) \sigma.
\]

Let \(\lambda\) be as in Theorem as in 5.1. Then with probability at least \(1 - \frac{(2e \log M - e)c'}{(\log M)^{1+\delta}}\), for any solution \(\hat{\beta}\) of problem (2.2) we have

\[
\frac{1}{\sqrt{T}} \|\hat{\beta} - \beta^*\|_{2,\infty} \leq \frac{c}{\sqrt{n}} \sqrt{\frac{(\log M)^{1+\delta}}{n}}.
\]

If, in addition, it holds that

\[
\min_{j \in J(\beta^*)} \frac{1}{\sqrt{T}} \|\beta^*_j\| \geq \frac{2c}{\sqrt{n}} \sqrt{\frac{(\log M)^{1+\delta}}{n}},
\]

then with the same probability for any solution \(\hat{\beta}\) of problem (2.2) the set of indices

\[
\hat{J} = \left\{ j : \frac{1}{\sqrt{T}} \|\hat{\beta}_j\| > c \sqrt{\frac{(\log M)^{1+\delta}}{n}} \right\}
\]

estimates correctly the sparsity pattern \(J(\beta^*)\):

\[
\hat{J} = J(\beta^*).
\]
The proofs of these theorems are similar to the ones of Theorems 3.1 and 4.1 up to a modification of the bound on \(P(A^c)\) in Lemma 3.1. We consider now the event

\[
A = \left\{ \max_{j=1}^{M} \sqrt{\sum_{t=1}^{T} \left( \sum_{i=1}^{n} (x_{ti})_j W_{ti} \right)^2} \leq \lambda nT \right\}.
\]

The Markov inequality yields that

\[
\Pr(A^c) \leq \sum_{t=1}^{T} \mathbb{E} \left[ \max_{1 \leq j \leq M} (\sum_{i=1}^{n} (x_{ti})_j W_{ti})^2 \right].
\]

Then we use Lemma A.2 given below with the random vectors

\[
Y_{ti} = ((x_{ti})_1 W_{ti}/n, \ldots, (x_{ti})_M W_{ti}/n) \in \mathbb{R}^M,
\]

\(\forall i \in \mathbb{N}_n, \forall t \in \mathbb{N}_T\). We get that

\[
\Pr(A^c) \leq \frac{2e \log M - e}{\lambda^2 nT} \frac{1}{nT} \sum_{t=1}^{T} \sum_{i=1}^{n} \max_{1 \leq j \leq M} |(x_{ti})_j|^2.
\]

By the definition of \(\lambda\) in Theorem 5.2 and Assumption 5.1 we obtain

\[
\Pr(A^c) \leq \frac{(2e \log M - e) c'}{(\log M)^{1+\delta}}.
\]

Thus, we see that under the finite variance assumption on the noise, the dependence on the dimension \(M\) cannot be made negligible for large \(T\).

A Auxiliary results

Here we collect two auxiliary results which are used in the above analysis. The first result is a useful bound on the tail of the chi-square distribution.

**Lemma A.1.** Let \(\chi^2_T\) be a chi-square random variable with \(T\) degrees of freedom. Then

\[
\Pr(\chi^2_T > T + x) \leq \exp \left( -\frac{1}{8} \min \left( x, \frac{x^2}{T} \right) \right)
\]

for all \(x > 0\).

**Proof.** By the Wallace inequality [Wallace 1959] we have

\[
\Pr(\chi^2_T > T + x) \leq \Pr(N > z(x)),
\]

where \(N\) is a standard normal variable. By the central limit theorem, we have

\[
\Pr(N > z(x)) \leq \exp \left( -\frac{1}{8} \min \left( x, \frac{x^2}{T} \right) \right).
\]

Therefore, we get

\[
\Pr(\chi^2_T > T + x) \leq \exp \left( -\frac{1}{8} \min \left( x, \frac{x^2}{T} \right) \right).
\]
where $N$ is the standard normal random variable and $z(x) = \sqrt{x - T \log(1 + x/T)}$. The result now follows from inequalities $\Pr(N > z(x)) \leq \exp(-z^2(x)/2)$ and

$$u - \log(1 + u) \geq \frac{u^2}{2(1 + u)} \geq \frac{1}{4} \min(u, u^2), \forall u > 0.$$

The next result is a version of Nemirovski’s inequality (see [Dümbgen et al. 2008], Corollary 2.4 page 5).

**Lemma A.2.** Let $Y_1, \ldots, Y_n \in \mathbb{R}^M$ be independent random vectors with zero means and finite variance, and let $M \geq 3$. Then

$$\mathbb{E} \left[ \left| \sum_{i=1}^n Y_i \right|_\infty^2 \right] \leq (2e \log M - e) \sum_{i=1}^n \mathbb{E} \left[ \left| Y_i \right|_\infty^2 \right],$$

where $| \cdot |_\infty$ is the $\ell_\infty$ norm.
