ABSTRACT

DiGeorge syndrome is a congenital genetic disorder that affects the endocrine system, mainly the thymus and parathyroid glands. The syndrome produces different symptoms, which vary in severity and character between patients. It manifests with craniofacial dysmorphism and defects in the heart, parathyroid, and thymus. Patients can present with a palatal deformity and nasal speech. This rare entity is caused mainly due to deletion of chromosome 22q11.2. Radiographic evaluation of DiGeorge syndrome is necessary to define aberrant anatomy, evaluate central nervous system, craniofacial abnormalities, musculoskeletal system, and cardiothoracic contents. It also helps in planning surgical procedures and surgical reconstructions. We report a case of DiGeorge syndrome in a 4-month-old neonate and discuss the clinical, imaging, and cytogenetic findings that helped in the diagnosis of this rare entity.

Key words: Endocrine, hypocalcemia, thymus

INTRODUCTION

DiGeorge syndrome (DGS) is a disease of the immune system. A patient with this condition is prone to develop infections due to poor T-cell formation and function. DGS is a lifelong condition whose symptoms can be seen in infants and children. This rare syndrome results in hypocalcemia arising from parathyroid hypoplasia, thymic hypoplasia, and outflow tract defects of the heart. DGS mainly results from deletion of chromosome 22q11.2. In this case report, we discuss the radiological features, laboratory findings, and the cytogenetic results that aided in the diagnosis of this rare syndrome.

CASE REPORT

A 4-month-old infant presented with complaints of cough, cold, and breathlessness that had persisted for 2 days. The baby’s oral intake had been very poor the earlier day. Initial clinical examination revealed bilateral wheeze on auscultation and subtle dysmorphic facial appearance which included small chin, small mouth, and coarse facial features. The mother gave history of uneventful postnatal period. The baby had received all the necessary vaccines required for her age. The mother...
also gave history of abortion of her previous pregnancy during the 2nd trimester because of cardiac anomaly identified on fetal ultrasound (USG) scan. In view of its difficulty in breathing, the baby was admitted to the intensive care unit (ICU) and was started on oxygen and nebulization. Nasopharyngeal aspirate showed positivity for respiratory syncytial virus (RSV) bronchiolitis. Blood gas analysis showed respiratory acidosis. In view of respiratory distress and acidosis, the baby was intubated and started on synchronized intermittent mandatory ventilation (SIMV) mode. Blood cultures were negative. Echocardiogram (ECHO) was done and found to be normal. Chest radiograph frontal projection showed bilateral air space opacities with right upper lobe consolidation suggestive of pneumonia [Figure 1]. The baby was started on antibiotics and oral Ribavirin. During the next day in ICU, the child had seizures. Biochemistry analysis showed reduced calcium level of 5.7 mg/dl (normal value: 8.5–10.1 mg/dl). 25-Hydroxy-vitamin D level was low and measured 13.4 ng/ml (normal value: <20 ng/ml). The parathyroid hormone (PTH) level was normal in spite of the low calcium. The baby was started on 1,25-dihydroxycholecalciferol and calcium. Blood investigations showed low hemoglobin measuring 7.5 g/dl (normal value: 11–14 g/dl) and a total WBC count of 10,700 cells/ml. Polymerase chain reaction (PCR) blood analysis showed positivity for cytomegalovirus (CMV). Flow cytometry of lymphocytes showed combined T-cell and B-cell immunodeficiency. In spite of good antibiotic cover and physiotherapy, the right upper lobe consolidation was persistent. Intravenous immunoglobulin and steroids were started to treat persistent infection, following the hematologist’s advice. Computed tomography (CT) of the chest with intravenous contrast showed hypoplastic thymus [Figure 2a] and right upper lobe consolidation [Figure 2b]. CT chest with maximum intensity projection (MIP) and volume-rendered (VR) images showed aberrant right subclavian artery [Figure 3a and b]. In view of dysmorphic facial features, chest infection, hypoplastic thymus, immunodeficiency, hypocalcemia, and decreased vitamin D, with a previous history of abortion of the fetus because of cardiac anomaly, a strong possibility of DGS was suspected. Fluorescent in situ hybridization (FISH) study was done to look for chromosomal defects. The results showed deletion of chromosome 22q11.2 [Figure 4], which confirmed the diagnosis of this rare entity. The baby’s respiratory distress gradually settled and the infant was discharged on the parent’s request.

Figure 1: 4-month-old infant with cough and expectoration, diagnosed with DiGeorge syndrome. Frontal radiograph shows consolidation involving the right upper zone (arrow).

Figure 2: 4-month-old infant with cough and expectoration, diagnosed with DiGeorge syndrome. (a) Contrast-enhanced axial image of CT chest in mediastinal window shows absent thymus (asterisk). (b) Non-contrast axial image of CT chest in lung window shows consolidation involving the right upper lobe (right arrow).

Figure 3: 4-month-old infant with cough and expectoration, diagnosed with DiGeorge syndrome. (a) CT scan-coronal maximum intensity projection (MIP) in arterial phase of chest shows aberrant right subclavian artery (asterisk). (b) CT scan volume-rendered image shows aberrant right subclavian artery (asterisk).

Figure 4: 4-month-old infant with cough and expectoration, diagnosed with DiGeorge syndrome. Fluorescent in situ hybridization (FISH) study shows deletion of chromosome 22q11.2 (arrow).
DISCUSSION

DiGeorge Syndrome (DGS) is a rare genetic disorder which can cause a wide array of symptoms. The diagnosis is often missed or delayed because pregnant women are not routinely screened for this rare entity. Hence, in any neonate with congenital hypocalcemia, recurrent infection, and seizure with absent parathyroid and thymus gland evident on imaging, a suspicion of DGS should arise and a detailed radiological, clinical, and cytogenetic examination should be carried out to avoid unnecessary complications.

It is estimated that approximately 90% of patients with the clinical diagnosis of DGS have a deletion of a specific portion of chromosome number 22 at position 22q11.2, called a microdeletion. This microdeletion is identified by a blood test called FISH analysis. The FISH test has made the diagnosis of DGS more precise and accurate. Approximately 90% of 22q11.2 deletions occur spontaneously and have not been passed on from the mother or father of the child. But once the diagnosis has been made, genetic counseling is critical and testing should be offered to parents and other family members.

Managing DGS needs a multidisciplinary approach and the cause for each symptom should be identified and treated accordingly. In our case, there was thymic hypoplasia (as evident in CT imaging) with decreased T lymphocyte production which, in turn, caused the B lymphocytes to produce insufficient antibodies; hence, immunoglobulin therapy and antibiotics were administered. Blood investigations revealed low calcium and vitamin D levels; appropriate calcium and vitamin D supplements were administered.
