(Dated: August 2012)

New physics thresholds which can modify the diphoton and dilepton Higgs branching ratios significantly, may also provide new sources of $CP$ and lepton flavor violation. We find that limits on electric dipole moments impose strong constraints on any $CP$-odd contributions to Higgs diphoton decays, unless there are degeneracies in the Higgs sector that enhance $CP$-violating mixing. We exemplify this point in the language of effective operators, and in simple UV-complete models with vector-like fermions. In contrast, we find that electric dipole moments and lepton flavor violating observables provide less stringent constraints on new thresholds contributing to Higgs dilepton decays.

1. INTRODUCTION

The recent discovery of a Higgs-like resonance at the LHC$^{[1]}$, with a mass of approximately 125 GeV consistent with electroweak precision observables, has solidified the impressive verification of the Standard Model (SM) at the electroweak scale. At the present time, the couplings of this resonance agree on average rather well with those of the SM Higgs boson.

The lack of hints for New Physics (NP) in other channels has focused attention on the detailed properties of the Higgs-like resonance, and deviations from the SM in its decays to various final states. Indeed, while the LHC now strongly constrains NP that can be produced either resonantly or in pairs from proton constituents with well-identifiable final states – e.g. $Z$ either resonantly or in pairs from proton constituents

LHC now strongly constrains NP that can be produced in its decays to various final states. Indeed, while the Higgs-like resonance, and deviations from the SM

the Higgs decay that can escape EDM bounds. In Sec. 3, we turn our attention to the $(H^+ H) L_i H_i^c$ operators contributing to dilepton decays, and consider the benchmark sensitivity from lepton flavor-violating (LFV) observables and EDMs. Section 4 contains some concluding remarks.

2. EDMS VS DIPHOTON DECAYS

Consider new physics charged under SU(2)$\times$U(1) only, so that the leading dimension-6 operators which correct the diphoton branching ratio of the Higgs are

$$
\Delta \mathcal{L} = \frac{g_1^2}{8 \Lambda^2} H^+ H \left( a_b B_{\mu\nu} B^{\mu\nu} + \tilde{a}_b B_{\mu\nu} \tilde{B}^{\mu\nu} \right) + \frac{g_2^2}{8 \Lambda^2} H^+ H \left( b_b W_{\mu\nu} W^{\mu\nu} + \tilde{b}_b W_{\mu\nu} \tilde{W}^{\mu\nu} \right)
$$

$$
\rightarrow \frac{c_h v}{\Lambda^2} h F_{\mu\nu} F^{\mu\nu} + \frac{\tilde{c}_h v}{\Lambda^2} h F_{\mu\nu} \tilde{F}^{\mu\nu} + \cdots
$$

Here $c_h = a_b + \tilde{a}_b$, $\tilde{c}_h = \tilde{a}_b + b_b$, $v = 246$ GeV and we have only retained the $h\gamma \gamma$ operators, disregarding couplings to $Z$ and $W$. Since we focus on corrections that are sizable for loop-induced couplings to the photon, the associated corrections to the tree-level $hZZ$ and $hWW$ couplings can be consistently ignored. For thresholds in the TeV range or above, measurement of the Higgs decay rate itself probably provides the best sensitivity to $\Lambda$. However, EDMs can provide sensitivity to the $CP$-odd threshold $\Lambda$. 

\[\text{arXiv:1208.4597v1 [hep-ph] 22 Aug 2012}\]
The ensuing correction to the SM $h \to \gamma\gamma$ width,
\[
\Gamma_{\gamma\gamma}^{\text{SM}} = \frac{m_h^3}{4\pi} \left( \frac{\alpha}{4\pi} \right)^2 \frac{|A_{\text{SM}}|}{2v}^2 \simeq 9.1 \text{ keV},
\]
takes the form
\[
R_{\gamma\gamma} = \frac{\Gamma_{\gamma\gamma}}{\Gamma_{\gamma\gamma}^{\text{SM}}} \simeq 1 - c_h \frac{v^2}{\Lambda^2} \frac{8\pi}{\alpha A_{\text{SM}}} + \left[ \frac{v^2}{\Lambda^2} \frac{8\pi}{\alpha A_{\text{SM}}} \right]^2,
\]
where $A_{\text{SM}}(m_h) = 125 \text{ GeV} \simeq A_W + A_\theta \simeq -6.5$ is proportional to the SM amplitude [12]. The deviations in the width are of $O(1)$ for $\Lambda/\sqrt{\Lambda} \sim 5 \text{ TeV}$. Note that since the $CP$-odd operator does not interfere with the SM amplitude, the corresponding correction to the diphoton branching ratio is necessarily positive and scales as $O(1/\Lambda^4)$.

A. EDM limit on contact operators

Current experiments [8,11] already probe the EDMs of elementary particles at a level roughly commensurate with two-loop electroweak diagrams [13], with the chirality of light particles protected by factors of $m_{\psi(q)}/v$. Thus it is useful to introduce the auxiliary quantity $d_f^{(2)}$ that quantifies this two-loop benchmark EDM scale,
\[
d_f^{(2)} = \frac{|e| a_m f}{16 \pi^2 v^2} \implies d_f^{(2)} \simeq 2.5 \times 10^{-27} \text{ e} \cdot \text{cm}. \tag{5}
\]
One observes that $d_f^{(2)}$ has already been surpassed by the current electron EDM limits [8,9], with the mercury [10] and neutron [11] EDMs not lagging far behind for $d_i^{(2)}$ [13].

The $CP$-odd Higgs operator [2] generates fermionic EDMs via a Higgs-photon loop,
\[
d_i = \hat{e}_h \frac{|e|m_f}{4\pi^2 \Lambda^2} \ln \left( \frac{\Lambda_{\text{UV}}^2}{m_h^2} \right) \tag{6}
\]
\[
= d_f^{(2)} \times \frac{\hat{e}_h}{\alpha/(4\pi)} \times \frac{v^2}{\Lambda^2} \ln \left( \frac{\Lambda_{\text{UV}}^2}{m_h^2} \right), \tag{7}
\]
with explicit dependence on the UV scale $\Lambda_{\text{UV}}$. If this scale is identified with $\hat{\Lambda}$, then using the current bound on the electron EDM, $|d_e| < 1.05 \times 10^{-27} \text{ e} \cdot \text{cm}$ [8], we find
\[
\hat{\Lambda} \gtrsim 50 \sqrt{\hat{e}_h} \text{ TeV}. \tag{8}
\]
Translating this to the Higgs diphoton branching ratio results in the conclusion that $CP$-odd corrections are limited by
\[
\Delta R_{\gamma\gamma}(\hat{e}_h) \lesssim 1.6 \times 10^{-4}. \tag{9}
\]
However, this conclusion can be relaxed in specific UV completions. As we discuss in the next subsection, the logarithm $\ln(\hat{\Lambda}^2/m_h^2) \sim 10$ cannot generally be stretched all the way to 50 TeV, as the loops of VL charged particles provide a much lower cutoff, while certain degeneracies may provide more significant qualitative changes to the implications of EDM limits.

B. UV complete examples with VL fermions

1. Singlet scalar with pseudoscalar coupling to VL fermions

We will now consider a specific UV completion which allows the full 2-loop function to be taken into account for the electron EDM. The addition of a (hyper)charged VL fermion $\psi$ with mass $m_\psi$ transforming as $(1, 1, Q_\psi)$ under $SU(3) \times SU(2) \times U(1)$, and a singlet $\tilde{S}$ with a Higgs-portal interaction with the Higgs doublet $H$ [14], leads to the following Lagrangian,
\[
L_{S\psi} = \bar{\psi} \gamma^\mu (i\gamma_\mu - e Q_\psi A_\mu) \psi + \bar{\psi} \left[ m_\psi + \hat{S} (Y_S + i\gamma_5 \tilde{Y}_S) \right] \psi + L_{HS}. \tag{10}
\]
The terms in $L_{HS}$ contain scalar kinetic terms and describe the Higgs-portal interaction between $\tilde{S}$ and $H$ via the following potential,
\[
V_{HS} = -\mu_H^2 H^\dagger H + \lambda_H (H^\dagger H)^2 + \frac{1}{2} m_\tilde{S}^2 \tilde{S}^2 + AH^\dagger H \tilde{S} - B \tilde{S} + \frac{\lambda_S}{4} \tilde{S}^4. \tag{11}
\]
$CP$-odd couplings of the Higgs proportional to the combination $AY_S$ are generated, while the term linear in $\tilde{S}$ can always be adjusted to ensure $\langle \tilde{S} \rangle = 0$. We retain only the photon contribution of the $J_\mu^S$ vector current, as the $Z$ contribution is suppressed by the small value of $g_V$. After the breaking of $SU(2) \times U(1)$, the $\tilde{S}$ field mixes with what would be the SM Higgs boson $\tilde{h}$ to produce two mass eigenstates $h$ and $S$,
\[
\begin{pmatrix}
\hat{h} \\
\hat{S}
\end{pmatrix} = \begin{pmatrix}
c_\theta & s_\theta \\
-s_\theta & c_\theta
\end{pmatrix} \begin{pmatrix} h \\ S \end{pmatrix}, \quad \tan 2\theta = \frac{2A v}{m_S^2 - 2A H v^2}, \tag{12}
\]
where $s_\theta$ ($c_\theta$) stands for $\sin \theta$ ($\cos \theta$). Both mass eigenstates inherit Higgs-like interactions with the SM fields and couplings to $\psi$ fermions.

The dominant two-loop contribution to fermion EDMs is well-known [13], and specializing to our case we arrive at the following result for the electron EDM as a function of $Y_S$, $\theta$ and $m_\psi$,
\[
d_f = d_f^{(2)} Q_\psi^2 \tilde{Y}_S \frac{v}{m_\psi} \sin(2\theta) \left[ g(m_\psi^2/m_h^2) - g(m_\tilde{S}^2/m_h^2) \right], \tag{13}
\]
where the loop function is given by
\[
g(z) = \frac{z}{2} \int_0^1 dx \frac{1}{x(1-x) - z} \ln \left( \frac{x(1-x)}{z} \right), \tag{14}
\]
which satisfies $g(1) \sim 1.17$ and $g \sim \frac{1}{2} \ln z$ for large $z$.

It is instructive to consider different limits of $m_h \sim m_\psi, m_S$, to logarithmic accuracy $g(m_\psi^2/m_h^2) - g(m_\tilde{S}^2/m_h^2) \rightarrow \frac{1}{2} \ln (m_{\text{min}}^2/m_h^2)$, where $m_{\text{min}}$ is the smaller of $m_S$ and $m_\psi$. In this limit, the heavy fields can be integrated out sequentially, with $S$ and $\psi$
first, and $h$ second. The first step is simplified by the use of the chiral anomaly equation for $\psi$, $\partial_\nu \bar{\psi} \gamma^\mu \gamma_5 \psi = 2i \bar{\psi} \gamma_5 \psi + \frac{2\pi}{s} Q^2 F_{\mu\nu} \tilde{F}_{\mu\nu}$. This leads to the following identification,

$$\frac{\tilde{c}_h}{\Lambda^2} = \frac{\alpha Q^2}{4\pi} \frac{\bar{Y}_S A}{m^2_S m_\psi}; \quad \Lambda_{UV} \simeq \min(m_{S}, m_\psi).$$

Apart from a smaller value for the logarithmic cutoff, the result in this limit differs little from the contact operator case above. Even if the value of the logarithm is not enhanced, $\ln(m_{S}^2/m_h^2) \sim O(1)$, the corrections to the Higgs diphoton rate will be limited to at most the sub-percent level unless a fine-tuned cancellation of $d_e$ is arranged with some other $CP$-odd source.

We now consider a different near-degenerate limit, $|m_h - m_{S}| \ll m_h$, which turns out to be more interesting as it allows the EDM constraints to be bypassed. If the difference between the masses is small, we can approximate

$$\sin(2\theta)(m^2_S - m_h^2) \rightarrow 2Av,$$

and the EDM becomes

$$d_f = d_f^{(2)} \times Q^2 \bar{Y}_S \frac{2Av m_\psi}{m_h^2} g'(m_\psi^2/m_h^2)$$

$$\rightarrow d_f^{(2)} \times Q^2 \bar{Y}_S \frac{Av}{m_\psi^2 m_\psi},$$

where in the final step we made use of the large $m_\psi$ limit.

The limiting case (17) receives no logarithmic enhancement. Moreover, the value of the $A$ parameter can be very small, comparable to the mass splitting between $h$ and $S$ or less. An $O(1)$ GeV mass splitting would naturally place $Av^2/(m_\psi^2 m_\psi)$ in the $O(10^{-4})$ range, suppressing the EDM safely below the bound.

At the same time, as explicitly shown in Ref. [5], modifications to the $h \rightarrow \gamma\gamma$ rate can be significant, and enhancement can come from the $F_{\mu\nu} \tilde{F}_{\mu\nu}$ amplitude. Unlike corrections to the $F_{\mu\nu} F_{\mu\nu}$ amplitudes that can enhance or suppress the effective rate, the $CP$-odd channel always adds to $R_{\gamma\gamma}$. Assuming that the mass difference between the singlet and the Higgs is small enough that they cannot be separately resolved (which requires $|m_{S} - m_h| \lesssim 3$ GeV with current statistics [5]), the apparent increase in the diphoton rate in this model is

$$R_{\gamma\gamma}^\text{eff} = \cos^2 \theta \times \frac{B_{h \rightarrow \gamma\gamma}}{B_{h \rightarrow \gamma\gamma}^\text{SM}} + \sin^2 \theta \times \frac{B_{S \rightarrow \gamma\gamma}}{B_{h \rightarrow \gamma\gamma}^\text{SM}}.$$  

If $\theta$ is in the range

$$\sqrt{\frac{\Gamma_{S \rightarrow \gamma\gamma}}{\Gamma_{h \rightarrow \gamma\gamma}}} \frac{B_{h \rightarrow \gamma\gamma}^\text{SM}}{B_{S \rightarrow \gamma\gamma}^\text{SM}} \lesssim \theta \lesssim \sqrt{\frac{\Gamma_{h \rightarrow \gamma\gamma}}{\Gamma_{S \rightarrow \gamma\gamma}}},$$

and $\Gamma_{h \rightarrow \gamma\gamma} \sim \Gamma_{S \rightarrow \gamma\gamma}$ then $R_{\gamma\gamma}$ simplifies to a $\theta$-independent expression,

$$R_{\gamma\gamma}^\text{eff} \simeq 1 + \frac{\Gamma_{S \rightarrow \gamma\gamma}}{\Gamma_{h \rightarrow \gamma\gamma}}.$$  

The rate for the weak eigenstate $\hat{S}$ to decay to two photons via its pseudoscalar coupling to the VL fermions is

$$\Gamma_{\hat{S} \rightarrow \gamma\gamma} = \frac{\alpha^2 Q^4 \bar{Y}_S^2 m_\psi^2}{256 \pi^2 m_\psi^2} \left[ A_{1/2} \left( \frac{m_\psi^2}{m_\psi^2} \right) \right]^2$$

with

$$A_{1/2} (\tau) = \frac{2}{\tau} \left( \sin^{-1} \sqrt{\tau} \right)^2.$$

For large $m_\psi$ the apparent diphoton increase can then be expressed as

$$R_{\gamma\gamma}^\text{eff} (\hat{Y}_S) \sim 1 + Q^4 \left( \frac{\bar{Y}_S}{2} \right)^2 \frac{(150 \text{ GeV})^2}{m_\psi^2}.$$  

A sizable increase in the apparent diphoton rate is seen to require rather large Yukawa couplings or light VL fermions. The VL leptons must be heavier than $10^5$ GeV to avoid limits from LEP. Their decay channels are fairly model-dependent but they are well within the reach of the LHC if they are at all relevant for the $h \rightarrow \gamma\gamma$ rate. For more discussion on experimental searches for such VL fermions, see [5].

In Fig. 1 we show the relationship between the electron EDM and the enhancement to the Higgs diphoton rate that comes from the operator $h F_{\mu\nu} \tilde{F}_{\mu\nu}$ for both the contact operator and nearly degenerate singlet cases. In the case of the contact operator, we show two cutoffs, $\Lambda_{UV} = 200$ GeV and 1 TeV. As seen in Sec. 2A it is apparent that in this simple situation, any appreciable increase in the $h \rightarrow \gamma\gamma$ rate must be accompanied by a value of the electron EDM that is in conflict with the present experimental limit. We also show the relationship between $R_{\gamma\gamma}^\text{eff}$ and $d_e$ in the singlet case for two values of the mixing angle, $\theta = 0.1$ and $\pi/4$, fixing the pseudoscalar Yukawa to $\bar{Y}_S = 2$ and choosing $Q_\psi = 1$. Different values of $R_{\gamma\gamma}^\text{eff}$ and $d_e$ then correspond to different values of $m_\psi$. It is now apparent that a sizable increase in the effective diphoton rate can be obtained in this model without inducing a value of the electron EDM that is presently excluded, demonstrating a UV-completion of the effective interaction that evades the constraints implied by a simple analysis of this contact operator. The reason that the EDM constraints are evaded in this case is clear: mixing of the two fields, $\hat{h}$ and $\hat{S}$, due to the small mass difference can proceed rather efficiently even with a small value of $A$, while the EDM loop diagrams do not enjoy the same resonant enhancement. In this model, for fixed $R_{\gamma\gamma}^\text{eff}$, $d_e$ increases with increasing $\Delta M$ and $\sin 2\theta$. The rough upper limit on $\Delta M$ of around 3 GeV with current data implies an upper limit on $d_e$ of $\sim 10^{-28} \text{ e cm}$ for $R_{\gamma\gamma}^\text{eff} \sim 1.5 - 2$. Separately resolving a degeneracy near 125 GeV or limiting the size of a potential mass splitting with more data clearly has important implications for EDM searches.
FIG. 1. The effective increase in the diphoton rate as a function of the electron EDM coming from a coupling of the Higgs to $F_{\mu\nu}F^{\mu\nu}$. The black dashed lines show the relationship in the case of the contact operator $hF_{\mu\nu}F^{\mu\nu}$ simply cut off at the scales $\Lambda_{\text{UV}} = 200$ GeV and 1 TeV. The solid lines show the relationship in the case of a scalar singlet, $S$, nearly degenerate with the Higgs coupled to a VL fermion, $\psi$. We choose a splitting between $m_S$ and $m_h$ of $\Delta M = 1$ GeV (left panel) and 3 GeV (right panel) and a $CP$-odd Yukawa coupling of the singlet to the VL fermions of $\bar{\psi} L$. The curve on the left of each panel (green) is for a mixing angle $\theta = 0.1$ and that on the right of each panel (blue) for $\theta = \pi/4$. The dotted lines show the value of $d_e$ implied for the two mixing angles for $m_\psi = 105$ GeV and 300 GeV. Values of the electron EDM that are excluded experimentally, $d_e > 1.05 \times 10^{-27}$ e cm, are in the shaded region. We observe that the degenerate scalar allows for a sizable apparent increase in the Higgs diphoton rate in the $CP$-odd channel while not conflicting with the electron EDM limit, unlike the simple contact operator case.

2. Full VL generation with $CP$-violating Higgs couplings.

Another simple UV completion is a full VL generation of SM-like fields $E_R \sim (1,1,-1)$ and $L_L \sim (1,2,-1/2)$, with their mirror image fields $E_L$ and $L_R$,

$$-\mathcal{L}_{EL} \supset (\bar{E}_L, L_L) \left( \begin{array}{c} M_E \\ y_2 H^* \\ M_L \end{array} \right) \left( \begin{array}{c} E_R \\ L_R \end{array} \right) + \text{h.c.} (25)$$

Every entry in this mass matrix, $M_{E(L), y_1(2)}$, can be complex. However, there is only one physical $CP$-odd phase combination that cannot be removed by a field redefinition $\sim \phi_E + \phi_L - \phi_1 - \phi_2$, which will appear in Higgs-fermion $CP$-odd vertices. For the purposes of calculation, it is more convenient to switch to the mass eigenstate basis for the $Q = 1$ fermions (we denote the masses $m_1$ and $m_2$), related to the original basis by a unitary rotation of the left- and right-handed fields.

In the mass eigenstate basis, the Higgs fields develop the following couplings to the $\psi_1$ and $\psi_2$ fermions,

$$\mathcal{L} = \frac{h}{2v} m_1 \bar{\psi}_1 \left[ 1 - \cos(2\theta_L) \cos(2\theta_R) - \frac{m_2}{m_1} e^{-i(\phi_L - \phi_R) \sin(2\theta_L) \sin(2\theta_R)} \right] \psi_{1R}$$

$$+ \frac{h}{2v} m_2 \bar{\psi}_2 \left[ 1 - \cos(2\theta_L) \cos(2\theta_R) - \frac{m_1}{m_2} e^{i(\phi_L - \phi_R) \sin(2\theta_L) \sin(2\theta_R)} \right] \psi_{2R} + \text{h.c.} + \cdots (27)$$

The ellipsis denotes the off-diagonal $h \psi_1 \bar{\psi}_2$ couplings, which will not affect the EDMs or Higgs decay phenomenology within our approximations. The $CP$-odd vertices from this Lagrangian can now be inserted directly into the two-loop formulae,

$$d^{(2)}_c = \frac{g(\phi_L - \phi_R) \sin(2\theta_L) \sin(2\theta_R)}{z_1 - g(\phi_L - \phi_R)} \left[ \frac{m_1 m_2}{m_h^2} \left( \frac{g(z_1)}{z_1} - \frac{g(z_2)}{z_2} \right) \right], \quad (28)$$
where $z_i = m_i^2/m_H^2$. In addition to the $h\gamma$ two-loop diagram, there is also a $WW$ two-loop contribution, with the same topology. The mass of the neutral fermion that enters this diagram is given by $m_{L_i}$, where

$$|M_L|^2 = m_L^2 \cos^2 \theta_L \cos^2 \theta_R + m_R^2 \sin^2 \theta_L \sin^2 \theta_R + \frac{m_1 m_2}{2} \cos(\phi_L - \phi_R) \sin(2\theta_L) \sin(2\theta_R).$$

$(29)$

$CP$ violation enters the $WW$ diagram via the relative phase of the left- and right-handed charged currents. Performing the calculation, we find

$$d_e^{WW} = d_e^{(2)} \times \sin(\phi_L - \phi_R) \sin(2\theta_L) \sin(2\theta_R) \times \frac{m_1 m_2 \alpha_W}{m_W^2 8\alpha} \left[ j(z_1, z_L) \frac{z_1}{z_1} - j(z_2, z_L) \frac{z_2}{z_2} \right],$$

$(30)$

Calculations of these two-loop effects closely resemble those for the two-loop charenguino-neutralino EDM contributions in ‘split SUSY’ models [16] and the two-loop EDMs in theories with additional $CP$-violating in the top-Higgs coupling (see, e.g., [17]).

In this model, the increase in the Higgs diphoton decay rate resulting from $CP$-violating couplings is

$$R_{\gamma\gamma}(\phi_L - \phi_R) = 1 + \left( \frac{d_e}{d_e^{(2)}} \right)^2 \frac{|m_2 A_{1/2}^p (m_h^2/4m_1^2) - m_1 A_{1/2}^p (m_h^2/4m_2^2)|^2}{4m_1 m_2 |A_{SM}|^2 D},$$

$(32)$

where $D$ is a (typically $O(1)$) combination of two-loop functions,

$$D = \frac{m_1 m_2}{m_h^2} \left[ g(z_1^h) - g(z_2^h) \right] + \frac{m_1 m_2 \alpha_W}{m_W^2 8\alpha} \left[ j(z_1^W, z_L^W) \frac{z_1^W}{z_1^W} - j(z_2^W, z_L^W) \frac{z_2^W}{z_2^W} \right].$$

$(33)$

A large enhancement of the diphoton rate through $CP$-violating effects would require large mass splittings between $\bar{\psi}_1$ and $\psi_2$ and for $d_e/d_e^{(2)}$ to be at least a factor of a few. Since $d_e^{(2)}$ is itself larger than the present limit on the electron EDM, a sizable $CP$-odd enhancement to the $h \to \gamma\gamma$ rate in this model will generate an electron EDM in conflict with experiment. Therefore, this model is an example of a UV-completion that gives rise to the operator $hF_{\mu\nu}F^{\mu\nu}$ whose behavior aligns with that of the simple contact operator in Sec. 2A; a large $CP$-odd contribution to the Higgs diphoton rate conflicts with the experimental limit on the electron EDM.

---

1 We note that a large splitting is problematic for electroweak precision measurements but a detailed analysis of this issue lies outside the scope of this paper. Studies of electroweak precision and an increase in the Higgs diphoton rate have recently been undertaken in, e.g., [13][14].
A. Flavor sensitivity

We assume a generic flavor structure for the matrices $\alpha_{ij}$ and $\beta_{ij}$. Integrating out the Higgs, the operators with minimal Yukawa suppression are 2-loop transition dipoles with top and W loops [18].

$$L_{\text{dipole}} = \frac{ae}{32\pi^3 v^2} (C_t + C_W) \tilde{l}_i F \sigma (\alpha_{ij} + i\beta_{ij} \gamma^5) l_j.$$ (38)

The loop functions are

$$C_t = 2N_c Q_t^2 f(z_t),$$ (39)
$$C_W = -\left\{ 3f(z_W) + \frac{23}{4} g(z_W) + \frac{3}{4} h(z_W) + \frac{1}{2z_W} [f(z_W) - g(z_W)] \right\},$$ (40)

where $z_t = m_t^2/m_H^2$, $z_W = m_W^2/m_H^2$, $g(z)$ is defined in Eq. [14] and

$$f(z) = \frac{z}{2} \int_0^1 dx \frac{1 - 2x(1-x)}{x(1-x) - z} \ln \left( \frac{x(1-x)}{z} \right),$$ (41)
$$h(z) = z^2 \frac{\partial}{\partial z} \left( \frac{g(z)}{z} \right).$$ (42)

There are also 1-loop contributions to the dipoles with an $h - \tau$ loop, proportional (with our normalization) to $Y_t^2$, and Higgs-mediated 4-fermion interactions that are further Yukawa-suppressed.

Using the effective interactions arising from (34), various LFV transition rates are straightforwardly computed as discussed e.g. in [21, 27], and we summarize some of the stronger limits in Table I. The transition dipoles generally lead to the strongest constraints, despite being generated at 2-loop order, as they are not subject to additional Yukawa suppression. Indeed, the largest contribution to $\mu \to e$ conversion actually comes from the induced $\mu e \gamma$ vertex, despite being loop suppressed relative to the Higgs-mediated 4-fermion operator.

We observe that most of the LFV limits are relatively weak, particularly in the $\tau$ sector, and so thresholds that impact $\text{BR}(h \to \tau\tau)$ could still introduce new flavor structures in the $\tau$ sector. The most stringent limits apply to $\alpha_{12}$ and $\beta_{12}$, and a generic flavor structure in the muon sector would limit branching ratio corrections to the percent level.

B. CP sensitivity

There are analogous 2-loop contributions to the electron EDM,

$$d_e = \frac{ae}{16\pi^3 v^2} \left( C_t + C_W \right).$$ (43)

The current electron EDM bound [8] implies $|\beta_{11}| < 0.13$. Taken as a generic flavor-independent limit, this would restrict any CP-odd corrections to the branching ratio to $O(2\%)$.

C. Comments on UV completions

A simple candidate model that can give rise to the effective Higgs-lepton interactions in (34) is a two Higgs doublet model [28] with one doublet, $H_d$, coupled to quarks and the other, $H_u$, to leptons. The charged Higgses, if light, could contribute to the branching rate to diphotons. However, substantially increasing this rate appears to require large, negative quartic couplings, with potential issues for vacuum stability. For further discussion of this point in the context of colored particles contributing to the diphoton rate, see [29].

The relatively weak limits on flavor-violating observables could allow for $O(1)$ deviations in the Higgs sector with respect to leptons. Measuring the Higgs decay rate to taus would be a highly desirable step towards testing this possibility. Looking for lepton flavor-violating decays with a large sample of taus, as could be obtained at a Super-B factory, would shed further light on the situation. Additionally, we note that it appears possible to

---

2 We include only the leading diagrams involving virtual W/goldstone bosons.
check the $CP$ properties of the $h - \tau - \tau$ coupling at a linear collider [30].

4. CONCLUDING REMARKS

With the discovery of a new Higgs-like resonance at the LHC, attention is turning to precision tests of its interactions. The variety of decay channels accessible at $\sim 125$ GeV is already providing important information about its couplings to vector bosons and fermions. Further tests of these production and decay channels in coming years will provide an important new probe of physics beyond the SM, and allow for a useful interplay with other precision data, particularly in the Yukawa sector.

In this paper, we have studied the extent to which a generic new threshold with $\gamma\gamma$ interactions to many cases. In particular, large $CP$-violating contributions to $h \rightarrow \tau\tau$ decays, large corrections to the SM rate are possible with new flavor structures at relatively low scales. Progress in studies of rare $\tau$-decays, e.g. at a Super-$B$ factory, could provide further constraints on this possibility.

Note: As this work was being finalized, several related publications appeared on the arXiv. Reference [31] discusses $CP$-odd contributions to Higgs digamma decays in models with VL fermions, while Refs. [32] consider the $CP$-properties of the Higgs-like resonance. We also thank P. Winslow for informing us of related work in progress with S. Tulin.

ACKNOWLEDGMENTS

We would like to thank B. Batell for helpful discussions. The work of D.M., M.P. and A.R. is supported in part by NSERC, Canada, and research at the Perimeter Institute is supported in part by the Government of Canada through NSERC and by the Province of Ontario through MEDT.
