Abstract
The set of realizable refractive indices as a function of frequency is considered. For passive media we give bounds for the refractive index variation in a finite bandwidth. Special attention is given to the loss and index variation in the case of left-handed materials.

1. Introduction
During recent years several new types of artificial materials or metamaterials with sophisticated electromagnetic properties have been designed. The fabrication of custom structures with dimensions much smaller than the relevant wavelength has made it possible to tailor the effective electric permittivity $\epsilon$ and the magnetic permeability $\mu$. For example, materials with thin metal wires simulate the response of a low-density plasma so that Re $\epsilon$ may become negative in the microwave range [1]. Similarly, with the help of a split-ring structure, a strong magnetic resonance is achieved so that Re $\mu$ may be negative [2]. Passive media with Re $\epsilon$ and Re $\mu$ simultaneously negative, first realized by Smith et al [3], are particularly interesting. Such materials are often referred to as left-handed, since, for negative $\epsilon$ and $\mu$, the electric field, the magnetic field and the wave vector form a left-handed set of vectors. As the Poynting vector and the wave vector point in opposite directions, the refraction at the boundary to a regular medium is negative. The concept of negative refraction, introduced by Veselago in 1968 [4], has opened a new horizon of applications in electromagnetics and optics. In particular the possibility of manipulating the near-field may have considerable potential, enabling imaging with no limit on the resolution [5].

Materials with negative $\epsilon$ and $\mu$ are necessarily dispersive [4,6], and loss is unavoidable. Loss has serious consequences in the performance of certain components; for example, it has been shown that the resolution associated with the Veselago–Pendry lens is strongly dependent on the loss of the material [7,8]. Therefore, it is important to look for metamaterial designs with negative real part of the refractive index while the loss is low. In this paper, instead of performing a search in an infinite, complex design space, we will find ultimate, theoretical bounds based on causality. We will also find optimal $\epsilon(\omega)$ and $\mu(\omega)$ functions. For example, suppose our goal is refractive index close to $-1$ while the loss is negligible in a limited bandwidth $\Omega = [\omega_1, \omega_2]$. What is then the minimal variation of the refractive index in $\Omega$, given that the medium is passive? If we force the real part of the refractive index to be exactly $-1$ in $\Omega$, what will then be the minimal loss there?

It is common to assume that the medium can be described by some specific model, such as single or multiple Lorentzian resonances. While this permits a straightforward analysis, it is not clear if a more general medium would give a more optimal response in some sense. We will therefore not use a specific model but rather assume only causality.

2. Realizable electromagnetic parameters
Any electromagnetic medium must be causal in the microscopic sense; the polarization and magnetization cannot precede the electric and magnetic fields, respectively. This means that $\epsilon(\omega)$ and $\mu(\omega)$ obey the Kramers–Kronig relations. In terms of the susceptibilities $\chi = \epsilon - 1$ or $\chi = \mu - 1$, these relations can be written as

$$\text{Im} \chi = \mathcal{H} \text{Re} \chi,$$

$$\text{Re} \chi = -\mathcal{H} \text{Im} \chi,$$

where $\mathcal{H}$ denotes the Hilbert transform [9]. These conditions are equivalent to the fact that $\chi$ is analytic in the upper half-plane (Im $\omega > 0$) and uniformly square integrable in the closed
upper half-plane\(^1\). The susceptibilities are defined for negative frequencies by the symmetry relation

$$\chi(-\omega) = \chi^*(\omega),$$

so that their inverse Fourier transforms are real. For passive media, in addition to (1)–(3) we have

$$\text{Im} \chi(\omega) > 0 \quad \text{for} \quad \omega > 0.$$  \((4)\)

The losses, as given by the imaginary parts of the susceptibilities, can be vanishingly small; however, they are always present unless we consider vacuum \([6]\).

Equations (1)–(4) imply that \(1 + \chi\) is zero-free in the upper half-plane \([6]\). Thus the refractive index \(n = \sqrt{\epsilon_0/\mu}\) can always be chosen as an analytic function in the upper half-plane. With the additional choice that \(n \to +1\) as \(\omega \to \infty\), \(n\) is determined uniquely, and it is easy to see that (1)–(4) hold for the substitution \(\chi \to n - 1\).

While any refractive index with positive imaginary part can be realized at a single frequency, the conditions (1)–(4) put serious limitations on what is possible to realize in a limited bandwidth to have a constant index less than unity. In particular we will analyse to what extent designing materials with the real part of the refractive index

$$\frac{\chi(\omega)}{\Delta n} = \frac{\chi(\omega)}{\Delta \chi},$$

and imaginary parts of \(\chi\) can be realized at a single frequency, the conditions (1)–(4) have a meaning in the upper half-plane. With the additional choice that \(n \to +1\) as \(\omega \to \infty\), \(n\) is determined uniquely, and it is easy to see that (1)–(4) hold for the substitution \(\chi \to n - 1\).

As an example, consider the case where the goal is refractive index close to \(-1\) in an interval \(\Omega\) with \(\Delta \ll 1\). In the limit of zero imaginary index, (8) shows that the variation of the real index in the interval is larger than \(4\Delta\). It is interesting that the minimal variation is obtained approximately if the medium has sharp Lorentzian resonances for a low frequency. For example, let \(\epsilon(\omega) = \mu(\omega) = 1 + \chi(\omega)\), where

$$\chi(\omega) = \frac{F_0^2}{\omega_0^2 - \omega^2 - i\alpha\Gamma}.$$  \((11)\)

Here, \(F_0\), \(\alpha_0\) and \(\Gamma\) are positive parameters. If the bandwidth \(\Gamma\) and centre frequency \(\omega_0\) are much smaller than \(\alpha_0\), \(\text{Re} n(\omega) \approx 1 - F_0(\omega_0/\omega)^2\) and \(\text{Im} n(\omega) \approx F_0\alpha_0\Gamma/\omega^3\) for \(\omega \gg \omega_0\). If we require \(\text{Re} n(\omega_1) = -1\), we obtain \(\text{Im} n(\omega_1) \approx 2\Gamma/\alpha_0\) and \(\text{Re} n(\omega_2) - \text{Re} n(\omega_1) \approx 4\Delta\). When \(\Gamma/\alpha_0 \to 0\), this corresponds to the optimal refractive index function associated with bound (8). Furthermore, it is worth noting that if we want the real index variation to be zero in \(\Omega\), the maximum imaginary part of the refractive index in \(\Omega\) must be larger than \(2\Delta\). The required imaginary part in \(\Omega\) can be roughly approximated by weak resonances at \((\omega_1 + \omega_2)/2\) (see figure 1).

So far we have considered the case where the goal is a constant \(u(\omega) < 0\) in \(\Omega\). If the goal is \(u(\omega) > 0\) in \(\Omega\), it is the last term in (5) that comes to rescue. Inspired by the result (7), we may let \(u(\omega)\) approach a delta function at a frequency much larger than \(\omega\). Indeed, in the limit where this resonance frequency approaches infinity, the function \(u(\omega)\) is constant and positive in \(\Omega\) while \(v(\omega)\) is zero. Of course this limit is not realistic; in practice, the resonance frequency is limited to, say, \(\omega_{\text{max}}\), where \(\omega_{\text{max}} > \omega_2\). The associated bounds are easily deduced along the same lines as above. For example, (8) becomes

$$u(\omega_2) - u(\omega_1) > u(\omega_1)\frac{\omega_2^2 - \omega_1^2}{\omega_{\text{max}} - \omega_1^2},$$

\(\Delta n = (\omega_2 - \omega_1)/\omega_2\). These bounds are realistic in the sense that equality is obtained asymptotically when \(v(\omega)\) approaches a delta function in \(\omega = 0\). In this limit \(u(\omega) = u(\omega_1)\omega_1^2/\omega^2\).

\(1\) If the medium is conducting at zero frequency, the electric \(\chi\) is singular at \(\omega = 0\). Although \(\chi\) is not square integrable in this case, similar relations as (1) and (2) can be derived \([6]\).
to a constant value was obtained recently [11]. While the latter bound means that \( n < \omega_c / \Omega_1 \) the required \( v(\omega) \) bandwidth, the required \( u(\omega) / \omega \) also that this bound is tight. A similar bound was obtained around \( \omega_0 \), we immediately find that the derivative \( d^2u/d\omega^2 \) is bounded from below:

\[
\frac{du}{d\omega} > \begin{cases} 
\frac{2|\mu(\omega)|/\omega}{\omega} & \text{for } u(\omega) < 0, \\
0 & \text{for } u(\omega) \geq 0, 
\end{cases}
\]

(13)

For the case \( u(\omega) \geq 0 \) we have set \( u_{\max} = \infty \). Note also that this bound is tight. A similar bound was obtained previously for \( \epsilon(\omega) \) and \( \mu(\omega) \) [6]. Equation (13) should also be compared with the weaker bound \( du/d\omega > -u(\omega)/\omega \) which was obtained recently [11]. While the latter bound means that the group velocities of transparent, passive media are bounded by \( c \), (13) implies the maximum group velocity \( c/(2 - n) \) for \( n < 1 \) (and \( c/n \) for \( n \geq 1 \)). Here \( c \) is the vacuum light velocity.

When the loss in a bandwidth \( \Omega \) is at most \( u_{\max} \), (13) becomes

\[
\frac{du}{d\omega} > \begin{cases} 
\frac{2|\mu(\omega)|/\omega - 4u_{\max}}{\pi \omega \Delta} & \text{for } u(\omega) < 0, \\
-\frac{4u_{\max}}{\pi \omega \Delta} & \text{for } u(\omega) \geq 0, 
\end{cases}
\]

(14)

to lowest order in \( \Delta \), for \( \omega \) close to \((\omega_0 + \omega_2)/2\). In obtaining (14) we have assumed that \( v(\omega) \) is approximately constant in \( \Omega \) and calculated the corresponding contribution to \( du/d\omega \).

A similar bound can be derived when \( v(\omega) \) varies slowly in \( \Omega \); for example, if \( v(\omega) \) is the imaginary part of a Lorentzian with \( \Gamma = \omega_2 - \omega_1 \), the inequality holds with the replacement \( 4/\pi \rightarrow 2 \). Note that without an assumption on the variation of \( v(\omega) \), \( du/d\omega \) can take any value.

A similar method as that leading to (8) can be used to find bounds for the variation of derivatives in \( \Omega \), in the limit of no loss. For the first order derivative, the variation can be arbitrarily small to first order in \( \Delta \), for any positive \( du(\omega_i)/d\omega \).

For negative second order derivative \( D \equiv d^2u/d\omega^2 \) (first order dispersion coefficient) we obtain

\[
D(\omega_2) - D(\omega_1) > |D(\omega_1)|4\Delta + O(\Delta^2).
\]

(15)

3. Discussion and conclusion

We have considered the set of realizable permittivities, permeabilities and refractive indices. For passive media we have used (1)–(4) to prove ultimate bounds for the loss and variation of the real part of the permittivity permeability and refractive index.

While the notation has indicated an isotropic medium, the bounds in this paper are valid for the effective index of the normal modes of anisotropic media as well. In fact, (1)–(4) with the substitution \( \chi \rightarrow n - 1 \) are valid under rather general circumstances: let \( x \in \mathbb{C} \) be a cartesian coordinate system. Provided an electromagnetic mode can be written \( A(x, y) \exp[\imath(\omega_{\text{loc}} z/c - \omega_{\text{lo}} t)] \), where \( n(\omega) \) is bounded and independent of \( z \) and the mode amplitude \( A(x, y) \) is independent of \( z \) and \( \omega, n(\omega) \rightarrow 1 \) satisfies the Kramers–Kronig relations (1) and (2). This can be realized using a similar argument as that in [9, 12].

On the basis of causality, it is clear that the susceptibilities of active media also satisfy (1)–(3). However, (4) is certainly not valid. Krein and Nudel’man have shown how to approximate a square integrable function in a finite bandwidth by a function satisfying (1)–(3) [13, 14]. The approximation can be done with arbitrary precision; however, there is generally a trade-off between precision and the energy of \( x \)

outside the interval [15]. Once a valid susceptibility has been found, a possible refractive index can be found, e.g. by setting \( n = \epsilon = \mu = 1 + x \). Hence, in principle, for active media \( n \) can approximate any square integrable function in a limited bandwidth.
