ABSTRACT

Using a large sample of Main Sequence stars with 7-D measurements supplied by Gaia and SDSS, we study the kinematic properties of the local (within ∼10 kpc from the Sun) stellar halo. We demonstrate that the halo’s velocity ellipsoid evolves strongly with metallicity. At the low [Fe/H] end, the orbital anisotropy (the amount of motion in the radial direction compared to the tangential one) is mildly radial with 0.2 < β < 0.4. However, for stars with [Fe/H] > −1.7 we measure extreme values of β ∼ 0.9. Across the metallicity range considered, i.e. −3 < [Fe/H] < −1, the stellar halo’s spin is minimal, at the level of 20 < vθ(kms^{-1}) < 30. Using a suite of cosmological zoom-in simulations of halo formation, we deduce that the observed acute anisotropy is inconsistent with the continuous accretion of dwarf satellites. Instead, we argue, the stellar debris in the inner halo were deposited in a major accretion event by a satellite with M_{vir} > 10^{10} M_⊙ around the epoch of the Galactic disc formation, i.e. between 8 and 11 Gyr ago. The radical halo anisotropy is the result of the dramatic radialisation of the massive progenitor’s orbit, amplified by the action of the growing disc.

Key words: Milky Way – galaxies: dwarf – galaxies: structure – Local Group – stars

1 INTRODUCTION

Stars in the Galactic halo formed earlier compared to those in the disc. However, the epoch of the halo assembly, i.e. the time at which these stars were deposited into the Milky Way, remains blurry. The onset of star-formation in the Galactic disc is bracketed to have happened between ∼8 and ∼11 Gyr ago, based on white dwarf cooling ages (see Oswalt et al. 1996; Leggett et al. 1998; Knox et al. 1999; Kilic et al. 2017), isochrone modelling (e.g. Haywood et al. 2013; Martig et al. 2016) and nucleocosmochronology (del Peloso et al. 2005). The birth times of the halo’s stellar populations can be estimated following the same procedures as for the disc. For example, it has been determined that the halo’s globular clusters range in age from ∼10 to ∼13 Gyr depending on metallicity (see e.g. Hansen et al. 2002, 2007; VandenBerg et al. 2013). Most dwarf spheroidals host stars nearly as old as the Universe itself (see Tolstoy et al. 2009), while many ultra-faint dwarfs appear to have formed the bulk of their stellar populations only slightly less than a Hubble time ago (see e.g. Belokurov et al. 2007; Brown et al. 2014). In the field, the halo stars have ages in the range of 10-12 Gyr (Jofré & Weiss 2011; Kilic et al. 2012; Kalirai 2012).

The first attempt to decipher the history of the formation of the Galactic disc and the stellar halo can be found in Eggen et al. (1962). Based on the strong apparent correlation between the metallicity of stars in the Solar neighborhood and the eccentricity of their orbits, the authors conclude that the metal-deficient stars formed first in an approximately spherical configuration. This original gas cloud then collapsed in a nearly instantaneous fashion, giving birth to the subsequent generations of stars. The contraction of the Galaxy not only yielded a population of younger stars on nearly circular orbits, but also profoundly affected the orbital shapes of the old stellar halo. As Eggen et al. (1962) demonstrate, driven by the collapse, the orbits of the halo stars ought to become highly eccentric, thus explaining the chemo-kinematic properties of their stellar sample. Later studies (see e.g. Norris et al. 1985; Beers & Sommer-Larsen 1995; Carney et al. 1996; Chiba & Yoshii 1998) revealed that the claimed correlation between the eccentricity and metallicity might have been caused by a selection bias affecting the dataset considered by Eggen et al. (1962). Notwithstanding the concerns pertaining to the observational properties of their data, the theoretical insights into the dynamics of the young Galaxy exposed by Eggen et al. (1962) are as illuminating today as they were 50 years ago.

Whilst the hypothesis of strict ordering of the orbital properties with metallicity in the stellar halo is not supported by the data, undeniably, a large fraction of the halo stars are metal-poor and do move on eccentric orbits. In spherical polar coordinates one

can characterize the shape of the stellar halo’s velocity ellipsoid by one number, the anisotropy parameter: $\beta = 1 - \frac{\sigma_r^2}{\sigma_\phi^2}$, where $\beta = -\infty$ for circular orbits and $\beta = 1$ for radial ones. In the Solar neighborhood, the halo’s velocity ellipsoid is evidently radially biased. For example, Chiba & Yoshii (1998) obtained $\beta = 0.52$ for a small sample of local halo red giants and RR Lyrae observed by the Hipparcos space mission. Using the SDSS Stripe 82 proper motions, and thus going deeper, Smith et al. (2009) measured $\beta = 0.69$ using $\sim 2,000$ nearby sub-dwarfs. Combining the SDSS observations with the digitized photographic plate measurements, Bond et al. (2010) increased the stellar halo sample further and derived $\beta = 0.67$. For slightly larger volumes probed with somewhat more luminous tracers, similar values of $\beta \sim 0.5$ were obtained (see e.g. Deason et al. 2012; Kafle et al. 2012). Unfortunately, beyond 15-20 kpc from the Sun, the behaviour of the anisotropy parameter is yet to be robustly determined. While there have been several attempts to tease $\beta$ out of the line-of-sight velocity measurements alone (see e.g. Sirko et al. 2004; Williams & Evans 2015), Hattori et al. (2017) have shown that these claims need to be taken with a pinch of salt. Curiously, the only distant stellar halo anisotropy estimate which actually relies on the proper motion measurements (with HST) reports a dramatic drop to $\beta \sim 0$ at $\sim 20$ kpc (see Deason et al. 2013b; Cunningham et al. 2016), albeit based on a very small number of stars.

Theoretically, the behavior of the orbital anisotropy in the dark halo has been scrutinized thoroughly. As demonstrated by Navarro et al. (2010), in the Aquarius suite of simulations, $\beta$ starts nearly isotropic in the centre of the galaxy, it reaches $\beta \sim 0.2$ around the Solar radius and keeps growing to $\beta \sim 0.5$ at $>100$ kpc, before falling again to zero around the virial radius. The picture gets somewhat muddled when the effects of the baryons are included. According to Debattista et al. (2008), halo contraction due to baryonic condensation may make the DM halos slightly more radially anisotropic, but overall, the changes are small and the $\beta$ trends with Galacto-centric distance are preserved. On the other hand, when the Aquarius halos are re-simulated with added gas physics and star-formation, only some galaxies retain their DM-only anisotropy trends, while in others, the $\beta$ profile flattens and stays constant with $\beta \sim 0.2$ throughout the galaxy (see Tissera et al. 2010). Even though, crudely, the physics of the formation and evolution of the dark and the stellar halos are the same, their redshift $z = 0$ properties may be drastically different due to the highly stochastic nature of the stellar halo accretion (see e.g. Cooper et al. 2010). Indeed, in numerical simulations of stellar halo formation, the anisotropy behavior differs markedly from that of the DM one. Already in the central parts of the Galaxy, $\beta$ quickly reaches $\sim 0.5$ and rises further to $\beta \sim 0.8$ at 100 kpc, showing a much smoother monotonic behavior all the way to the virial radius (see e.g. Abadi et al. 2006; Sales et al. 2007; Rashkov et al. 2013; Loebman et al. 2017).

In this paper, we explore the behavior of the stellar halo velocity ellipsoid as a function of metallicity and distance above the Galactic plane. Our sample is based on the SDSS DR9 spectroscopic dataset and consists of Main Sequence stars with distances between $< 1$ and $< 10$ kpc from the Sun. The stars included in the analysis overlap widely with selections considered by several groups previously (see Smith et al. 2009; Bond et al. 2010; Loebman et al. 2014; Evans et al. 2016). However, thanks to the Gaia DR1, the proper motions of these stars are now measured with an improved accuracy. Section 2 gives the details of the stellar sample under consideration, as well as the model used to characterize the stellar halo behavior. The implications of our findings and the comparison to the numerical simulations of the stellar halo formation are presented in Section 3.

2 DATA AND MODELLING

2.1 Main Sequence stars in SDSS-Gaia

We select Main Sequence stars from the SDSS DR9 spectroscopic sample (Ahn et al. 2012) by using the following cuts: $|b| > 10^\circ$, $A_g < 0.5$ mag, $\sigma_{RV} < 50$ kms$^{-1}$, S/N$ > 10$, $3.5 < \log(g) < 5$, $0.2 < g - r < 0.8$, $0.2 < g - i < 2$, $4500 < T_{eff} < 8000$ K and $15 < r < 19.5$. All magnitudes are de-reddened using dust maps of Schlegel et al. (1998). A total of 192,536 stars survives the above cuts. We estimate the stars’ distances using equations (A2), (A3) and (A7) in Ivezić et al. (2008). The proper motions are obtained using a crossmatch between the SDSS and Gaia catalogs. The SDSS catalog has been astrometrically recalibrated using the GaiaSource positions in order to correct both small and large scale systematic astrometric errors. The resulting SDSS-Gaia proper motion catalog covers the entirety of the high latitude SDSS sky with baselines between 6 and 18 years. Deason et al. (2017) and de Boer et al. (2018) assess the quality of the catalog and demonstrate that it suffers little from systematic biases and clearly outperforms the SDSS-Gaia catalogs relying on the original SDSS astrometric solution. For each star, given the position on the sky and the distance, the proper motion and the line-of-sight velocity are converted to Galacto-centric Cartesian velocity components assuming the Local Standard of Rest of 235 kms$^{-1}$ and the components of the Solar peculiar motion presented in Coşkunolu et al. (2011). The uncertainties in distance, line-of-sight velocity and proper motion are propagated using Monte-Carlo (MC) sampling to obtain the final uncertainties on the velocity components in spherical polar coordinates. Accordingly, for each star, its Galacto-centric coordinates and velocity components are the median values of the resulting MC distribution, and the associated “error-bars” are the Median Absolute Deviation values scaled up by a factor of 1.48. To remove the obvious outliers we cull 0.1% of stars with excessively high speeds. Note that the (magnitude-independent and metallicity-independent) proper motion uncertainties are estimated using equation (2) provided in Deason et al. (2017), (for further discussion also see de Boer et al. 2018). Furthermore, neither the
Co-formation of the Galactic disc and the stellar halo

Figure 2. Behavior of the velocity components in spherical polar coordinates, namely radial \( v_r \) and azimuthal \( v_\theta \), for stars in the SDSS-Gaia Main Sequence sample. The dataset is divided into metallicity bins, \([\text{Fe/H}]\), increasing from left to right and Galactic height bins, \(|z|\), increasing from top to bottom. The size of the median velocity error for each subset is shown in the top left corner of each panel and the total number of stars in that bin can be found in the top right corner. Pixel size is \(20 \times 20 \text{ kms}^{-1}\). The distribution of the metal-rich stars near the Galactic plane (top right corner of the panel grid) displays two distinct populations: a cold rotating one (the thick disc) and a barely rotating, markedly radially anisotropic one (the stellar halo). Moving from top to bottom, i.e. to greater heights, the Galactic disc contribution quickly diminishes. From right to left, i.e. from metal rich to metal poor, the stellar halo’s velocity ellipsoid evolves from strongly radial to significantly more isotropic.

selection procedure above nor the SDSS spectroscopic targeting scheme (with the exception of the K-giant sample not used here) include restrictions based on the stellar kinematics. Therefore, we believe that the sample considered here is kinematically unbiased. Figure 1 shows the density distribution of stars in our sample. A strong spatial bias due to the SDSS spectroscopic selection is clearly visible in the left panel, where stars can be seen reaching \(3 < R \text{ (kpc)} < 23\) and \(|z| < 9\) kpc. The right panel gives the distribution of the stellar metallicity as a function of the Galactic height. A metal-rich, i.e. \([\text{Fe/H}] \approx 0\) component corresponding to the Galactic disc is apparent at \(|z| < 1\) kpc. Curiously, a low-height density enhancement is also discernible at low metallicities, i.e. \([\text{Fe/H}] < -1\).

Besides the survey-induced systematics, there may exist other observational biases that could affect the measurements reported in this work. For example, a large and non-constant fraction of unresolved binary objects amongst the stars considered here could influence the kinematics in the following way. The stellar distances, as predicted by the equations in Ivezić et al. (2008) are appropriate for single stars. However, if instead a star is an unresolved binary, it will appear brighter at a fixed color as compared to the fiducial relation. This would in turn lead to an underestimated photometric distance and therefore underestimated tangential velocity. Despite the fact that all stars considered here have spectra, most of the potential binaries would remain undetected. This is because the fraction of stars with a clear spectroscopic binary signature (i.e. doubling of all absorption lines) is expected to be small, due to i) the low spectral resolution of the SDSS, and 2) because the binary star period distribution peaks at \(10^3\) days (see Raghavan et al. 2010), thus yielding minuscule line shifts. To understand the possible impact of the binarity on our results, we have carried out the following simple test. We have generated a mock stellar sample corresponding to an old (12 Gyr) metal-poor ([Fe/H]=-1) stellar population. The masses of the stars are drawn from the Chabrier IMF, their distances from \(\rho \propto r^{-2}\) radial density distribution (from 0.1 to 100 kpc) and their velocities from a Gaussian with a constant velocity dispersion of 100 kms\(^{-1}\). Assuming binary fractions of 0, 0.5 and 0.9 and a uniform mass ratio distribution (see Raghavan et al. 2010), we calculated the impact of the binaries on the measured tangential velocity dispersions. Reassuringly, for the substantial 50% binary fraction, only a 10% lower velocity dispersion is registered. For an unrealistically high 90% binary fraction, one would underestimate the tangential velocity dispersion by 20%. Accordingly, we believe that our velocity dispersion measurements (see below) are largely insensitive to the presence of unresolved binary stars in the sample.

2.2 7D view of the local stellar halo

Figure 2 shows the evolution of the azimuthal, \(v_\theta\), and the radial, \(v_r\), velocity components of the stellar sample defined in the previous subsection as a function of metallicity, \([\text{Fe/H}]\), and height above the Galactic disc, \(|z|\). Note that we use the spherical polar conven-
tion in which $\theta$ is the azimuthal angle and $\phi$ is the polar angle. In the Figure, the metallicity of the stars considered increases from left to right and the Galactic height grows from top to bottom. In the distributions of the stars closest to the Galactic plane (top row), two components with different kinematic properties are clearly discernible. The (thick) disc has a negligible mean radial velocity, $\bar{v}_r \sim 0$ km s$^{-1}$, and a significant rotation, $\bar{v}_\theta \sim 200$ km s$^{-1}$. Much hotter in terms of its velocity dispersion, especially in the $r$ direction, is the stellar halo whose rotation $\bar{v}_\theta$ is extremely weak. As the stars get progressively metal-poorer (from right to left), the rotating component fades, and disappears completely when observed at greater heights (middle and bottom row). Note that as shown in the top left corner of each panel, the velocity error changes strongly as a function of the Galactic $|z|$ and for the fixed $|z|$ is approximately constant across the entire metallicity range. The evolution of the error with height is driven by the dependence of the tangential velocity on distance and the distance error on the photometric uncertainty.

The most notable feature of Figure 2 is the appearance of the stellar halo ellipse. The halo’s distribution is demonstrated to be stretched dramatically in the radial direction for stars in the high metallicity range, i.e. for $-1.7 < [\text{Fe/H}] < -1$. However, at lower metallicity, it evolves rapidly to an almost spherical shape. To track the behavior of the stellar halo’s velocity ellipsoid, we model the stellar distributions shown in Figure 2 with a mixture of multi-variate Gaussians using the Extreme Deconvolution algorithm described in Bovy et al., (2011). Given that the number of stars and the complexity of the overall velocity distribution which evolves quickly as a function of metallicity and Galactic $|z|$, we use different numbers of Gaussian components for each sub-sample. The two lowest metallicity bins and the highest $|z|$ bin are always modelled with one 3D Gaussian (according to the number of the velocity dimensions in spherical polars). For all other subsets, in a 3x2 array in the top right corner of Figure 2 we attempt to fit three 3D Gaussian components. However, if the resulting component contains less than 3% of the total number of stars in a given sub-sample we do not report its properties. The uncertainties of the model parameters are estimated using the bootstrap method.

The results of the multi-Gaussian decomposition of the velocity distributions are shown in Figure 3. Here, the significant (i.e. containing $>3\%$ of total stars) model components are over-plotted on top of the model residuals for each sub-set in the metallicity and $|z|$ space. White solid lines give the projection of the disc’s velocity ellipsoid, and black solid lines show the main halo component. In four cases, two in the top and two in the middle row, a third halo-like Gaussian (white dashed) was required to describe the data: in these cases its contribution varied between 5% and 15% of the total number of stars in the bin. As displayed in the Figure, the overall quality of the fits is good, changing from excellent at the metal-poor end to satisfactory at the metal-rich extreme. Most metal-rich distributions show clear over-densities of stars with high radial velocities, both positive and negative. These high $v_r$ “lobes” are most visible in the two right columns of the Figure. Additionally, some smaller amplitude residuals are also discernible, e.g. for the stars.

**Figure 3.** Residuals (data-model) of the fit to the distributions shown in Figure 2. Dark (white) corresponds to an excess (depletion) of stars in the data compared to the model. The number of stars per pixel contributing to the highest positive (negative) residuals are shown in the right (left) corner of each panel. The Gaussian components used to describe the data are also shown: solid white for the disc, solid black for the main halo, and white dashed for the additional halo-like component. Note a clear pattern of excess-depletion-excess along the radially stretched halo component in the right hand side of the grid. The appearance of the metal-rich halo residuals clearly indicates that the observed velocity distribution is strongly non-Gaussian. Also note a small but discernible disc-like residuals in the top-left corner of the grid (corresponding to the metal-poor stars near the Galactic plane).
closest to the disc, in the most metal-rich bin (top right corner of the grid) and e.g. at $v_\theta \sim 150$ kms$^{-1}$ for the stars with lowest metallicity (top left corner and adjacent).

Figure 4 summarizes the evolution of the individual velocity dispersions $\sigma_r$, $\sigma_\theta$, and $\sigma_\phi$ (left) and the resulting orbital anisotropy (middle) of the stellar halo as a function of metallicity for three different Galactic height ranges. Also shown is the behavior of the rotation $v_\phi$ of the main halo (right). As hinted in the Figures 2 and 3, $\sigma_r$, $\sigma_\theta$, $\sigma_\phi$ and $\beta$ are all a strong function of the stellar metallicity. However, this dependence does not appear to be gradual. Instead, a sharp transition in the properties of the stellar halo’s ellipsoid can be seen at [Fe/H] $\sim -1.7$. For more metal-rich halo stars, the anisotropy is acutely radial, with $\beta$ reaching values of 0.9! However, the halo traced by the most metal-poor stars is almost isotropic with $0.2 < \beta < 0.4$. Note also that while a visual inspection of Figure 2 registers a noticeable swelling of the velocity ellipsoid with Galactic height. The amount of rotation in the metal-poor stars appears to evolve with $|z|$; however, as explained in the main text, this is largely the result of low but non-negligible disc contamination and over-simplified model (one Gaussian component for the two most metal-poor sub-samples).

3 DISCUSSION AND CONCLUSIONS

This Paper uses the SDSS-Gaia proper motions and thus our dataset is nearly identical to that of Myeong et al. (2018b,a). As shown by Deason et al. (2017) and de Boer et al. (2018), both random and systematic proper motion errors in the SDSS-Gaia catalog are minimized compared to most previously available catalogs of similar depth. Instead of attempting to identify a sub-sample of halo stars, we model the entirety of the data with a mixture of multivariate Gaussians. This allows us to avoid any obvious selection biases and extract a set of robust measurements of the stellar halo velocity ellipsoid. As seen by SDSS and Gaia, the properties of the local stellar halo are remarkable. We show that the shape of the halo’s velocity ellipsoid is a strong function of stellar metallicity, where the more metal-rich portion of halo, i.e. that with $|z| < 1.5$, exhibits extreme radial anisotropy, namely $0.8 < \beta < 0.9$ (see Figure 4). Co-existing with this highly eccentric and relatively metal-rich component is its metal-poor counterpart with $-3 < [\text{Fe/H}] < -1.7$ and $\beta \sim 0.3$. The velocity ellipsoid evolves rapidly from mildly radial to highly radial over a very short time. Co-formation of the Galactic disc and the stellar halo.
metallicity range, changing $\beta$ by $\sim 0.6$ over 0.3 dex. The two stellar halo components also display slightly different rotational properties. The more metal-enriched stars show a mild prograde spin of $\sim 25$ kms$^{-1}$ irrespective of Galactic height $z$. The spin of the metal-poor halo evolves from $\sim 50$ kms$^{-1}$ at $1 < |z|$ (kpc) $< 3$, to $\sim 20$ kms$^{-1}$ at $5 < |z|$ (kpc) $< 9$. Note, however, that while the stellar halo’s properties change sharply at [Fe/H] $\sim -1.7$, we do not claim that the more isotropic component does not exist at higher metallicities [Fe/H] $> -1.7$, it is just much weaker (see white dashed contours in Figure 3).

Before we discuss the implications of the measurements presented above for the genesis of the stellar halo, let us briefly compare the properties of the velocity ellipsoid deduced here to those in the literature. Most of the recently published halo anisotropy values are close to $\beta < 0.7$ (e.g. Smith et al. 2009; Bond et al. 2010; Posti et al. 2017), significantly lower than $\beta > 0.9$ reported here. We believe, however, that there is no obvious disagreement as previous estimates combine stars across the entire metallicity range and therefore represent an average over the [Fe/H]-dependent values we measure. In terms of the halo spin, the amount of prograde rotation at high $|z|$ is consistent with the majority of both the past and recent studies of the stellar halo (see e.g. Chiba & Beers 2000; Deason et al. 2017).

What could be the cause of the dramatic radial anisotropy registered at high metallicity and what is the nature of the striking bimodality in the behavior of the stellar halo presented in the previous section? The two currently available theories for the formation of the stellar halo in the vicinity of the Galactic plane invoke i) accretion and disruption of multiple satellites and ii) in-situ formation of a puffed-up rotating halo via the disc heating. However, it is hard to fathom how the observed extremely radial velocity anisotropy could be reconciled with either of these scenarios without any modification. We are not aware of any in-situ halo model where i) the resulting halo possesses highly radial anisotropy and ii) the rotation signal would be as low as measured here, i.e. $\sim 25$ kms$^{-1}$ (as judged by the metal-richer subset of our halo stars). Equally difficult to imagine is the idea that a prolonged accretion of multiple low-mass Galactic fragments can yield such high values of $\beta$. Given that the accreted satellites should show a diversity of orbital properties, it is more natural to expect a much more isotropic velocity ellipsoid, perhaps similar to what we observe at low metallicities, but wildly different from that of the metal-enriched stars, i.e. the bulk of the stellar halo near the Sun.

Recently, several arguments have been put forward to support the idea of the halo formation through a single dominant accretion event some $\sim 10$ Gyr ago (see e.g. Deason et al. 2013a; Belokurov et al. 2017). In this scenario, one massive merger provides the lion’s share of the halo stars within $\sim 30$ kpc of the Galactic center. At this characteristic radius (see e.g. Deason et al. 2011; Sesar et al. 2011), the properties of the stellar halo appear to change dramatically thus leading Deason et al. (2013a) to argue that this transition scale may correspond to the last apo-centre of the halo’s progenitor before disruption. The hypothesis in which a large portion of the inner Galaxy’s halo is dominated by the stellar debris from a massive satellite is consistent with the abundance patterns of light elements in the halo. The absence of prominent sequences corresponding to contributions from low-mass systems as well as the iron abundance at the characteristic “knee” of the stellar halo’s [$\alpha$/Fe] distribution (see e.g. Venn et al. 2004; Tolstoy et al. 2009; de Boer et al. 2014) could all be explained with the (early) accretion of a massive progenitor. This interpretation is also supported by the study of Amorisco (2017) who has built a large library of toy models of idealized merger events in an attempt to provide an atlas of the halo properties corresponding to different accretion histories. They confirm the conclusions of Deason et al. (2013a) that massive satellites are able to sink deeper in the potential well of the Galaxy due to dynamical friction, thus dominating the inner halo of the Galaxy. Additionally, Amorisco (2017) show that the evolution of the orbital properties of the in-falling dwarfs depends strongly on their mass: the low-mass systems might experience some mild orbital circularisation, while the orbits of the more massive systems tend to radialise rather strongly. Therefore, for high mass-ratio events, due to the pronounced orbital radialisation, the resulting stellar halo possesses negligible spin at redshift $z = 0$. This is in excellent agreement with the most recent measurement by Deason et al. (2017) and the results presented here.

We seek to verify the above hypothesis using a suite of numerical simulations which improve on those discussed in the literature so far (such as those by Bullock & Johnston 2005; Amorisco 2017). We consider 10 cosmological zoom-in simulations of the formation of the stellar halo around galaxy hosts with masses similar to that of the Milky Way. These simulations are described in detail in Jethwa et al. (2018) and Belokurov et al. (2017) and are run with the N-body part of GADGET-3 which is similar to GADGET-2 (Springel 2005). Our stellar halo realisations (based on tagging the most bound particles in satellites; De Lucia & Helmi 2008; Bailin et al. 2014) are similar to those presented in Bullock & Johnston (2005) and Amorisco (2017) in the way that they do not attempt to model the gas-dynamics and the feedback effects. Yet they contain some of the salient features nec-

Figure 5. Velocity anisotropy of the stellar debris in the Solar neighborhood ($4 < R$(kpc) $< 25$, roughly matching the range probed by the data) as a function of the progenitor’s accretion redshift for three different sub-halo mass ranges. Each data-point gives the median value across the suite of 10 simulations. The highest radial anisotropy (for the considered range of Galactocentric radii) is attained by the debris from the most massive progenitors ($M_{\text{vir}} > 10^{10}M_{\odot}$, red line) accreted between $z = 1$ and $z = 3$, i.e. during the disc growth phase (correspond to 8 to 11 Gyr of lookback time, grey shaded region). The error-bar on the left hand side gives an estimate of the typical scatter in an individual (redshift, mass) bin. In the inset, the black solid (grey dashed) line shows the distribution of final orbital eccentricity for the satellites with $M_{\text{vir}} > 10^{10}M_{\odot}$ and accretion redshift $1 < z < 3$ with (without) the baryonic disc included. Even without the action of the disc, the distribution of eccentricities has a peak at $e > 0.7$. The presence of the disc enhances the orbital radialisation, pushing the peak of the distribution to $e < 0.9$. 

MNRS 000, 000–000 (0000)
Co-formation of the Galactic disc and the stellar halo

Miyamoto & Nagai 1975; Hunt et al. 3; (Dehnen 2000; Kirby et al. 2013; Myeong et al. and Antoja et al. 2014 above. Most importantly, given that due to the selection effect of the orbital eccentricities of the subhaloes with $M_{\text{sub}}>10^{10} M_\odot$, we recover a small but statistically significant positive radial velocity for stars contributing to this disc-like population. This is consistent with the analysis of Myeong et al. (2018a) who also show that the excess of rotating metal-poor stars with $0< v_r (\text{kms}^{-1}) < 20$ is a strong function of Galactic-centric radius. Thus, it is unlikely that this signal is provided by a (thick) disc alone. Instead we conjecture that this could plausibly be a combination of an extremely metal-poor disc and stars trapped in a resonance with a bar, a feature known as the Hercules stream (see Dehnen 2000; Antoja et al. 2014; Hunt et al. 2018). At larger distances from the Galactic plane, the contribution of the disc at the metal-poor end sharply subsides and the velocity distribution can be adequately described with a single Gaussian, yielding spin values comparable (or sometimes slightly lower) to those observed at the metal-rich end.

An alternative explanation of the strong radial anisotropy observed in the stellar halo may be provided by the ideas of Eggen et al. (1962), i.e. by invoking a non-adiabatic mass growth which would result in an increase of orbital eccentricities in the halo. However, this dramatic contraction of the young Galaxy would affect all stars situated in the Milky Way at that time, irrespective of their metallicity. This can be contrasted with the measurements reported here: at the metal-poor end, a much lower velocity anisotropy is observed, $0.2< \beta < 0.4$. This nearly isotropic velocity ellipsoid can still be reconciled with the hypothesis of the collapse-induced radialisation if the metal-poor stars were either accreted after the prolific growth phase or stayed sufficiently far away from the portions of the Galaxy undergoing rapid transformation. However, as Figure 5 demonstrates, there may be a simpler explanation of the dependence of the velocity ellipsoid on the stellar metallicity. According to the Figure, moderate radial anisotropy appears consistent with the stellar debris contributed by the low-mass objects, irrespective of the accretion redshift. Thus, the Cosmological zoom-in simulations paint a picture in which the stellar halo dichotomy emerges naturally due to a correlation between the orbital properties of the accreted dwarfs and their masses.
