Abstract
We discuss how the surface gravity can be classically defined for dynamical black holes. In particular, we focus on defining the surface gravity for locally defined horizons and compare a number of definitions proposed in the literature. We illustrate the differences between the various proposals in the case of an arbitrary dynamical, spherically symmetric black hole spacetime. We also discuss how the trapping horizon formalism of Hayward can be related to other constructions.

1. Introduction

The relationship between black hole evolution and thermodynamics is one of the most widely studied topics in theoretical physics. Originally conceived in the context of purely classical evolution [1], the discovery of the semiclassical Hawking radiation effect put black hole thermodynamics on a firm theoretical footing. It enabled the surface gravity appearing in the laws of black hole mechanics to be related to the true thermodynamic temperature of a thermal spectrum.

The existence of Hawking radiation implies that the evolution of an astrophysical black hole throughout its lifetime will almost never be exactly static. Either the black hole will be growing by accreting matter, from either nearby matter sources or the cosmic microwave background, or it will be evaporating, albeit slowly, by the emission of Hawking radiation. For very small black holes it is expected that their evolution is highly dynamic with a large flux of radiation. To arrange for a black hole whose size is neither growing nor shrinking would require a fine balance between the amount of matter being accreted and the amount of energy being lost through Hawking radiation.

3 Current address: Center for Theoretical Physics, Seoul National University, Seoul 151-747, Korea.
Most derivations of the Hawking radiation effect assume quasi-stationary, quasi-equilibrium evolution. In fact, several derivations rely on the fact that the background spacetime is exactly static and ignore any backreaction from the energy flux of the radiation. However, it is expected that the Hawking radiation process will continue even in dynamical situations and, by consistency, the mere occurrence of Hawking radiation will, almost inevitably, lead to dynamical evolution of the black hole spacetime. Thus, it is imperative that the concepts underlying black hole thermodynamics be extended to dynamical situations. Equilibrium thermodynamics can reasonably only be expected for quasi-static processes. But even in quasi-static processes, no results should depend on exact staticity. In dynamical, non-equilibrium thermodynamics, results based on exact staticity cannot be trusted at all.

The thermodynamic analogy between black holes and thermodynamic systems suggests that we should equate the classical surface gravity to the temperature of the Hawking radiation. The surface gravity is defined classically in terms of the geometric properties of the underlying metric. What is surprising is that the same quantity shows up as the temperature of quantum fields in the Hawking effect. In a fully dynamical situation, the surface gravity will probably not be directly analogous to a temperature of any thermal spectrum. This is because in a fully dynamical situation the Hawking radiation is unlikely to be thermal since the black hole is no longer in thermal equilibrium. However, it is likely that something analogous to surface gravity will still have a role to play in dynamical spacetimes. Both in terms of defining an evolution law relating the change in mass of a system to its change in area and also in terms of governing the emission of Hawking radiation and the flux of the Hawking radiation. This generalization of surface gravity should reduce to the usual notion of surface gravity in exactly static spacetimes. It is to this issue that we turn in this paper.

We emphasize that in dynamical situations the surface gravity will probably not correspond exactly to a temperature. In non-static situations, the zeroth law of black hole mechanics will not hold exactly. One would expect for an evaporating black hole that the classically defined surface gravity will change as the black hole loses mass. In the thermodynamic analogy, this is an indication that the dynamical black hole is not in exact thermal equilibrium. If the evolution is slow enough on relevant timescales, then one may still talk about quasi-equilibrium evolution and define a thermal temperature. In a non-equilibrium, fully dynamical situation the temperature may not be well defined.

As noted above, the surface gravity is defined classically. It is defined in terms of purely geometric quantities, typically in terms of a Killing field. This means that, in standard treatments, it is only defined for exactly static situations. It is not even defined in quasi-static processes where one expects the evolution to be quasi-equilibrium and the Hawking radiation to be thermal. In fact, the usual definition of the surface gravity does not even hold in a spacetime that admits gravitational radiation anywhere in the spacetime.

The surface gravity actually plays two important but slightly different roles in black hole mechanics. The first is in the classical evolution law for the black hole, in the sense of the first law. This evolution law should hold independently of any quantum effects. It is a purely classical effect. The surface gravity plays the role of the ‘constant’ of proportionality between the change in the mass of the black hole and the change in the area. In order for this first law to be well defined, one has to be careful about how one defines the mass of the black hole. In this way, the definition of the surface gravity is closely connected to our choice of quasi-local mass.

The second role that the surface gravity plays is in the emission of Hawking radiation. One would expect a suitable generalization of the surface gravity to play some role in dynamical Hawking radiation, even in non-equilibrium processes. On would also expect that such a generalization should reduce in the static limit to the well-known static result. There have
been a number of derivations of the Hawking effect that are easily applicable to dynamical situations (see, for example, [2–4]). These derivations make it clear that the Hawking effect is a local geometrical effect and that something resembling the surface gravity plays a key role. Heuristically, one is tempted to think that the larger the surface gravity, the more Hawking radiation there will be and the quicker the black hole will evaporate. One may even be able to consider hypothetical situations where an extremal black hole grows dynamically without Hawking radiation, by the accretion of suitable matter.

The most widely known definition of the surface gravity is in terms of a Killing horizon. This is, for example, how the surface gravity is calculated for a Schwarzschild black hole. This works well in stationary situations but breaks down in fully dynamical situations, where no such Killing horizon exists. A key question is whether the surface gravity can be defined for black holes that are evolving, either by accreting matter or by emitting Hawking radiation.

In stationary spacetimes, the event horizon of a black hole is typically a Killing horizon for a suitably chosen Killing vector. However, for event horizons in more general, non-stationary spacetimes, the surface gravity can be defined in terms of the null generators of the horizon. In these more general cases there is no Killing vector field to use to fix the normalization of the surface gravity. Since the generator of the horizon is only really defined on the event horizon, there is no natural way of fixing this normalization by imposing a condition off the horizon.

However, recently much interest has focused on local definitions of horizons [5–7]. These local horizons are typically defined in terms of spacelike 2-surfaces for which the expansion of the outgoing null normal vanishes. Indeed, there are good reasons for believing that it is such a local horizon, and not the event horizon, that is responsible for the Hawking process [2, 4]. Since we expect the surface gravity to play a role in governing the ‘amount’ of Hawking radiation, it makes sense to investigate surface gravity definitions for local horizons in dynamical situations.

While there have been many proposals for what the dynamical surface gravity should be, there is not yet any consensus as to what the correct definition is. In this paper, we investigate a number of different definitions for the dynamical surface gravity that have appeared in the literature. In order to compare them, we will compute their forms for marginally trapped surfaces in a generic, dynamic, spherically symmetric spacetime. Furthermore, we will be able to evaluate how these definitions compare to the familiar Killing horizon definition in the static limit.

The results presented here will be of a purely classical nature based purely on the geometry of the spacetime. We will not perform any quasi-classical calculations involving quantum fields and we will not prove any relation between the classical surface gravity discussed here and any Hawking radiation that may be emitted, although such a relation is of course one of the main motivations for the work (for some results in this direction see [8]). We rather take the viewpoint that the surface gravity can be defined in a classical way and thus its nature is tied up with the local geometrical properties of the spacetime at the horizon.

The paper is organized as follows. In section 2, we give an overview of the various proposals that have appeared in the literature for defining surface gravity including for Killing horizons and event horizons. In section 3, we go on to compare these various definitions in the case of a fully general, dynamical, spherically symmetric spacetime. We then conclude with a discussion.

When working in advanced Eddington–Finkelstein coordinates we will use a dot to denote differentiation with respect to the time coordinate \(\nu\), thus \(\dot{m} = \partial_\nu m\), and a dash to denote differentiation with respect to the radial coordinate \(r\), thus \(m' = \partial_r m\). Greek superscripts and subscripts will denote components in a given coordinate basis, while Latin superscripts and subscripts denote tensor indices in the abstract index notation [9].
2. Surface gravity definitions

2.1. Surface gravity for Killing horizons and event horizons

The traditional definition of the surface gravity [1] is based on the idea of a Killing horizon, a hypersurface where a Killing vector of the metric becomes null. In general relativity, stationary event horizons are typically Killing horizons for a suitably chosen Killing vector $k^a$ (for the technical assumptions for this proposition see [10]). The surface gravity $\kappa$ of the Killing horizon can be defined by

$$k^a \nabla_a k^b = \kappa k^b.$$  \hspace{1cm} (1)

Thus, the surface gravity for a Killing horizon is defined by the fact that the Killing vector is a non-affinely parametrized geodesic on the Killing horizon. The proof of this is as follows: since $k^a k_a$ is constant and zero on the Killing horizon by definition, $\nabla_b (k^a k_a)$ must be normal to the horizon, in the sense of being orthogonal to any vector tangent to a curve lying in the horizon. Since $k^a$ is also normal to the horizon, and this normal is unique, we have $k^a \nabla_a k_a \propto k_b$. Using the Killing relation, we then obtain the above.

We note here, for later use, that due to Killing’s equation the above can also be written as

$$\frac{1}{2} g^{ab} k^c (\nabla_c k_a - \nabla_a k_c) = \kappa k^b.$$  \hspace{1cm} (2)

Since $k^a$ is normal to the null hypersurface, it is hypersurface orthogonal and by the Fröbenius theorem we have

$$k_{[a} \nabla_{b]} k_{c]} = 0.$$  \hspace{1cm} (3)

Contracting this condition (3) with $\nabla^a k^b$ and using the Killing property we get another formula often seen in the literature as a definition of the surface gravity [9],

$$\kappa^2 = -\frac{1}{2} (\nabla^a k^b)(\nabla_a k_b).$$  \hspace{1cm} (4)

There is also a nice physical interpretation of the surface gravity. In static spacetimes the surface gravity can be interpreted as the limiting force required at infinity to hold a mass stationary above the event horizon (one could imagine the mass connected to infinity by a very long massless string). Note that this physical interpretation does not work in non-static spacetimes [9].

By virtue of Killing’s equation $\nabla_a k_b + \nabla_b k_a = 0$, the Killing vector is only determined up to a constant factor. This freedom corresponds to a gauge freedom to rescale the curve parameter along the integral curves of the Killing vector by a constant factor. The advantage of using a Killing horizon of a global Killing vector field is that for static, asymptotically flat spacetimes, this factor can be fixed by requiring $k_a k^a = -1$ at infinity and thus, at infinity, the Killing vector coincides with the 4-velocity of a static observer parametrized by the observers proper time $\tau$. This fixes the freedom in $k^a$ globally and uniquely determines the value of the surface gravity of a Killing horizon.

This prescription can also be extended to apply to static observers anywhere in the spacetime and leads to the idea that the temperature of the event horizon tends to infinity as seen by static observers located closer and closer to the horizon. However, this procedure relies on a Killing vector field to relate the normalization at the horizon to a point away from the horizon.

A similar definition to (1) can be made for an event horizon that is not a Killing horizon, with the role of the Killing vector replaced by the null generator of the event horizon. However,

4 In general, off the horizon, the Killing vector is not geodesic.

5 A slightly different prescription is required for non-static spacetimes such as the Kerr solution, since the relevant Killing vector is no longer composed purely of a time-translational Killing vector. In this paper, we are only considering spherically symmetric spacetimes.
in the general case, there is no natural way to fix the parametrization of this generator. Even in spherically symmetric spacetimes, where the generators of the future event horizon will form a subset of the congruence of radially outgoing null geodesics, it is not easy to fix the parametrization of the generators and thus the value of the surface gravity.

2.2. Surface gravity for marginally trapped surfaces

In dynamical situations, it is a well-known fact that local definitions of horizons such as apparent horizons, trapping horizons or dynamical horizons do not necessarily coincide with the location of the event horizon. In such cases one is left with the question ‘for which surface should one define the black hole area or the black hole surface gravity?’ The canonical choice is to use the event horizon. However, as noted above, there is evidence that it is the apparent horizon, and not the event horizon, that plays the key role in Hawking radiation. This idea has become a key point in hopes to demonstrate Hawking radiation in the laboratory using analogue gravity models. Furthermore, it has been shown that the laws of black hole thermodynamics can easily be applied to the case of trapping and dynamical horizons.

Most of the definitions we will consider in this work are motivated by investigations of local horizons. Therefore we will evaluate the surface gravity for marginally outer trapped surfaces, although several of the definitions could equally well be applied to event horizons.

A marginally trapped surface is a compact spacelike 2-surface for which the expansion of one of the future-directed null normals vanishes. In the following, we will consider spacelike 2-surfaces with an ingoing null normal \( n^a \) and an outgoing null normal \( l^a \). Furthermore, we will assume that the cross-normalization of these two null vectors is such that \( l^a n_a = -1 \). A marginally outer trapped surface is therefore defined by the requirement that \( \theta_l = 0 \) where the expansion is given by

\[
\theta_l = g^{ab} \nabla_a l_b + n^a l^b \nabla_a n_b + l^a n^b \nabla_a l_b.
\]

A common approach to defining the surface gravity of a non-Killing horizon is to use the fact that \( l^a \) is typically a non-affinely parametrized geodesic on the horizon, although it is not always a horizon generator. This mirrors the requirement for a Killing horizon that the Killing vector should be a non-affinely parametrized null geodesic on the Killing horizon. In this way, the surface gravity can be defined via the equation

\[
l^a \nabla_a l^b = \kappa l^b,
\]

or

\[
\kappa = -n^b l^a \nabla_a l^b.
\]

While the direction of the null geodesic \( l^a \) will be fixed by the location of the horizon and its foliations into spacelike 2-spheres, the choice of the parametrization of \( l^a \) will become crucial to the overall value of the surface gravity.

Writing the null vector \( l^a \) as the tangent vector of a curve \( x^\mu(\lambda) \) with parameter \( \lambda \), under a change of parametrization of the curve \( \lambda \to \lambda' \), the components of the tangent vector change by

\[
l^\mu \equiv \frac{dx^\mu}{d\lambda} \to l'^\mu \equiv \frac{dx^\mu}{d\lambda'} = \frac{d\lambda}{d\lambda'} (x) l^\mu = \Omega(\lambda) l^\mu,
\]

6 This issue is actually quite subtle. In spacetimes satisfying the null energy condition, it has been conjectured by Eardley [11] that the outer boundary of the region containing marginally trapped surfaces is in fact the event horizon. However, in spherically symmetric spacetimes, with spherically symmetric slicings, the apparent horizon is in most cases also a dynamical horizon and a trapping horizon. In most dynamical cases it does not coincide with the location of the event horizon [12].

7 Note this change of parametrization can depend on the spacetime point \( x \).
and the surface gravity changes by

$$\kappa \rightarrow \kappa' = \frac{d\lambda'}{d\lambda}(x) \kappa + \lambda' \nabla \lambda'(x) = \Omega(x)\kappa + \lambda' \nabla \Omega(x). \tag{9}$$

If the surface gravity is to measure the extent to which the geodesic $l^a$ fails to be affinely parametrized, the choice of parametrization becomes essential. For a Killing horizon the normalization is fixed by the link between the parametrization of the Killing vector and the proper time at infinity.

For an affinely parametrized geodesic $\kappa = 0$. In general, the tangent vector $l^a$ can always be reparametrized to eliminate $\kappa$. However, a number of proposals have been made to fix the parametrization of this null vector and in order to give a non-zero surface gravity this parametrization is required to be non-affine. The following are some of the proposals that have been given for fixing this normalization.

Fodor et al. [14] proposed a non-local choice of normalization for spherically symmetric spacetimes in terms of an affinely-parametrized ingoing null geodesic $n^a$ whose asymptotic form was such that $t^an_a = -1$ where $t^a$ is the asymptotic time-translational Killing vector. In order to do this one needs to require that the spacetime admits an asymptotically flat spatial infinity. This choice of parametrization for ingoing $n^a$ is then transferred to the choice of the parametrization of outgoing $l^a$ by requiring the condition $l^an_a = -1$ everywhere in the spacetime. The proposal of [14] is therefore

$$\kappa_F = -n^b l^a \nabla_{alb}, \tag{10}$$

where $n^a$ must be affinely parametrized everywhere and at asymptotically flat spatial infinity by the proper time of static observers. Fodor et al. discuss how this normalization can be observed locally by measuring the frequency of fiducial photons sent in from infinity.

Hayward [15] gave a definition of the surface gravity for dynamic, spherically symmetric spacetimes in terms of the Kodama vector $K^a$ [16]. The Kodama vector has the property that the combination $K_a T^{ab}$ is divergence free in spherical symmetry and that $K^a$ reduces to $K^aK_a = -1$ at spatial infinity. The overall sign can be fixed by requiring it to be future directed. In static electrovac solutions it coincides with the time-translational Killing vector of the Reissner–Nordström geometry [15]. The value of the ‘dynamic surface gravity’ for a trapping horizon was defined by

$$\frac{1}{2} g^{ab} K^c (\nabla_c K_a - \nabla_a K_c) = \kappa_K K^b. \tag{11}$$

This matches the form of (2) but note that the Kodama vector does not in general satisfy Killing’s equation and it is not necessarily geodesic on the horizon. The surface gravity defined in this way is unique since $K^a$ is unique and agrees with the surface gravity in the Reissner–Nordström case. However, this definition does not agree with that given in [5] or [14] and is only applicable in spherically symmetric spacetimes.

For an isolated horizon, Ashtekar, Beetle and Fairhurst [17] fixed the normalization by setting the expansion of the ingoing null vector $n^a$ to be the same as the Reissner–Nordström value and cross-normalizing with $l^a$ via $n^a l_a = -1$. This idea was elaborated by Ashtekar, Fairhurst and Krishnan [18] by fixing $\kappa$ as a unique function of the horizon parameters $a_\Delta$ and $Q_\Delta$, in terms of the known value given in the static case. However, it is not possible to extend this method to situations such as Einstein–Yang–Mills where the surface gravity in the static sector is not a unique function of the horizon parameters.

In the case of a slowly evolving horizon, defined in terms of a perturbative expansion around an isolated horizon, Booth and Fairhurst [19] gave a new definition of the surface gravity that was an extension of the definition for isolated horizons. It is given by

$$\kappa_B = -B n^a l^b \nabla_{alb} - C l^a n^b \nabla_{bnb}, \tag{12}$$
where the normal to horizon is given by $\tau^a = Bl^a + Cn^a$. $B$ and $C$ are just scalar fields on the dynamical horizon that encode how the choice of a horizon normal (unique up to a factor) can be expressed in terms of the chosen $l^a$ and $n^a$. Clearly in the isolated horizon case, where $B = 1$ and $C = 0$, it reduces to the original isolated horizon definition. In addition, it is clear in this form that this definition incorporates information about the inaffinity of $l^a$, through the term $n^a l^b \nabla_b l_a$, and the inaffinity of $n^a$, through the term $l^a n^b \nabla_b n_a$.

It is also possible to define a surface gravity without appealing to the inaffinity of a null vector. This is usually done by identifying the surface gravity in a dynamical law for the black hole evolution. An analogue of the surface gravity, called trapping gravity, was presented by Hayward in [5]. In the notation used here it is given by

$$\kappa_H = \frac{1}{2} \sqrt{-n^a \nabla_a \theta_l}.$$

(13)

On a marginally outer trapped surface, where $\theta_l = 0$, this definition is independent of the parametrization of $l^a$ since under a reparametrization of $l^a$ by $\lambda \to \lambda'$, we have $l^a \to \frac{d\lambda}{d\lambda'} l^a, n^a \to \frac{d\lambda}{d\lambda'} n^a$ (since we require $n^a l_a = -1$) and $\theta_l \to \frac{d\lambda}{d\lambda'} \theta_l$.

Another definition of the surface gravity for a trapping horizon was proposed by Mukohyama and Hayward [20]:

$$\kappa_M = -\frac{1}{16\pi r} \int_S d^2 \theta \sqrt{h} \left( n^a \nabla_a \theta_l + l^a \nabla_a \theta_n + \frac{\theta_n}{\Lambda} l^a \nabla_a \Lambda \right).$$

(14)

Their original definition was also based on affinely parametrized null vectors. However, the original definition also included a factor of $l^a n_a$ which will not be $-1$ if both null vectors are affinely parametrized. Here we have introduced a factor $1/\Lambda$ that would make a general $l^a$ affinely parametrized. A full derivation of this result appears in appendix A. Since this formula involves an integral over the marginally trapped surface it is manifestly quasi-local. Once again this definition is independent of the parametrization of $l^a$, provided the normalization $n^a l_a = -1$ is preserved.

For a dynamical horizon [6], the effective surface gravity is identified from an area balance law [6] and takes the value

$$\frac{1}{2r} \frac{df(r)}{dr}$$

(15)

where $r$ is the area defining radial coordinate and $f(r)$ is any function of $r$. Once again there is freedom in the normalization that can usually be fixed by appeal to the stationary Kerr solution.

3. Surface gravity in dynamic, spherically symmetric spacetimes

To see how these various definitions compare to one another we turn now to a specific example of a dynamical, spherically symmetric metric. A general, dynamic, spherically symmetric metric can be written in advanced Eddington–Finkelstein coordinates\(^8\) as

$$\text{d}x^2 = -A^2(v, r) \Delta(v, r) \text{d}v^2 + 2A(v, r) \text{d}v \text{d}r + r^2 \text{d}\Omega^2,$$

(16)

The two free functions $A(v, r)$ and $\Delta(v, r)$ could in principle be determined by solving the full Einstein equations, although we will see here that this is not necessary for our purposes. The function $\Delta(v, r)$ can be written in terms of the Misner–Sharp mass function $m(v, r)$ as

$$\Delta(v, r) = 1 - \frac{2m(v, r)}{r}.$$

(17)

\(^8\) These coordinates will be well defined on the future horizon (but not the past horizon) and are therefore better suited to examining functions defined there than Schwarzschild coordinates. Painlevé–Gullstrand coordinates served a similar purpose in [12].
The function $A(v, r)$ will also play an important role in what follows and should not be confused with the area of the horizon. Note that, in general, the function $A(v, r)$ cannot be gauged away and a general spherically symmetric spacetime must contain two free functions [12]. In certain situations, such as the Schwarzschild and Reissner–Nordström solutions, one can consistently choose $A = 1$. However, in other situations, such as the Einstein–Skyrme system studied in [21], this function cannot be set equal to one everywhere and its value on the horizon will affect the value of the surface gravity computed in terms of a Killing horizon.

In the static case where $A$ and $\Delta$ are only functions of $r$ there is a Killing vector that is timelike for $\Delta > 0$. Suitably normalized this Killing vector has components $(1, 0, 0, 0)$ and thus on the Killing horizon, choosing the positive root, equation (4) gives

$$\kappa = \frac{A(r_H)}{2m(r_H)}(1 - 2m'(r_H)). \quad (18)$$

This we will take as the surface gravity of a spherically symmetric Killing horizon. We can now compare how this result for the Killing horizon compares with the various static limits of the proposed dynamical surface gravities in spherically symmetric spacetimes.

The first definition for a dynamical, non-Killing horizon, surface gravity proposed by Hayward in [5], is independent of the chosen normalization on the horizon:

$$\kappa_H = \frac{1}{2} \sqrt{-na \nabla_a \theta_l}. \quad (19)$$

For the spherically symmetric metric we have

$$na \nabla_a \theta_l = A\Delta - A'r \Delta - Ar^2 \Delta', \quad (20)$$

where $m' = \partial_r m$. Therefore, on the horizon $\Delta = 0$, we have

$$\kappa_H = \frac{1}{4m} \sqrt{1 - 2m'}. \quad (21)$$

This will reduce to the static result in situations where $A(r) = 1/\sqrt{1 - 2m'}$. However, as already noted in [14] this does not give the correct answer in the Reissner–Nordström case where $A = 1$ and $m' = Q^2/2(2M^2 - Q^2 + 2M \sqrt{M^2 - Q^2})$.

Fodor et al’s value [14] for the surface gravity $\kappa_F$ is simple to evaluate in Eddington–Finkelstein coordinates. The correctly normalized $n^\mu$ and $l^\mu$ are given by

$$n^\mu = (0, -1, 0, 0), \quad (22)$$

$$l^\mu = \left(1, \frac{A\Delta}{2}, 0, 0\right). \quad (23)$$

Therefore, we obtain

$$-n^\mu l^\nu \nabla_\nu I_\mu = \frac{\dot{A}r^2 + AA'r(r - 2m) + A^2(m - m' r)}{Ar^2}. \quad (24)$$

On the horizon this becomes

$$\kappa_F = \frac{A}{4m} (1 - 2m') + \frac{\dot{A}}{A}. \quad (25)$$

This definition will always give the Killing horizon value in static spacetimes, since in static cases $\dot{A} = 0$.

The Kodama vector in a spherically symmetric spacetime has the following form in Eddington–Finkelstein coordinates:

$$K^\mu = \left(\frac{1}{A}, 0, 0, 0\right). \quad (26)$$
In spherical symmetry we have
\[ g^{ab} K^c (\nabla_c K_a - \nabla_a K_c) = \left( \frac{\Delta A' + A \Delta'}{A}, \frac{\Delta(\Delta A' + A \Delta')}{A}, 0, 0 \right), \] (27)
on the horizon this becomes
\[ \frac{1}{2} \left( \frac{\Delta'}{A}, 0, 0, 0 \right) = \kappa_{K_a} K^a \] (28)
and thus we find
\[ \kappa_{K_o} = \frac{1}{4m} (1 - 2m'), \] (29)
which will reduce to the static, Killing horizon case when \( A = 1 \).

The value for the surface gravity \( \kappa_M \) given by Mukohyama and Hayward in [20] has the form
\[ \kappa_M = -\frac{r}{4} \left( l^a \nabla_a \theta_n + n^a \nabla_a \theta_l + \frac{\theta_n}{A} l^a \nabla_a \Lambda \right). \] (30)
Since we have
\[ l^a \nabla_a \theta_n = \frac{2 A r^2 + A^2 \Delta + A' A r \Delta}{A^2 r^3}, \] (31)
this gives
\[ \kappa_M = m \frac{1}{2} \left( \frac{1 - 2m'}{4m^2} - \frac{\Lambda}{A^2 m} \right) - \frac{r \theta_n}{4A} l^a \nabla_a \Lambda. \] (32)
Thus, the value of the surface gravity depends on knowing the factor \( \Lambda \) that makes \( l^a \) affinely parametrized. This will be discussed further in the appendix. In static situations, we have
\[ \Lambda = k A^2 \Delta, \] where \( k \) is a constant of integration, and thus
\[ \kappa_M = \frac{1}{4m} (1 - 2m'). \] (33)

The surface gravity for a slowly evolving horizon, proposed by Booth and Fairhurst in [19], does not fix the overall normalization of the surface gravity. The value of \( l^a n^b \nabla_b n_a \) depends on the choice of normalization for \( l^a \) and for affinely parametrized \( n^a \) in spherical symmetry (equation (22) above) we naturally find
\[ l^a n^b \nabla_b n_a = 0. \] (34)
However, for general parametrizations, transforming via \( l^\mu = \Omega(x) l^\mu \) we find
\[ l^a n^b \nabla_b n_a = n^a \nabla_a \Omega \frac{\Omega}{\Omega^2} + \frac{1}{\Omega^2} l^a n^b \nabla_b n_a. \] (35)
Thus, the surface gravity for a slowly evolving horizon depends on the choice of normalization and will only coincide with that given by the isolated horizon formula \( \kappa = -n^a l^b \nabla_b n_a \) if \( n^a \) is affinely parametrized or \( \Omega' = 0 \).

In [12] it was shown how the use of the Misner–Sharp mass can lead to a preferred normalization for the surface gravity in spherically symmetric spacetimes. As shown in [12] the surface defined by
\[ r = 2m(v, r) \] (36)
defines a marginally trapped surface at \( r = r_H \) and in many cases is also a dynamical horizon or trapping horizon. Differentiating this equation with respect to any parameter \( \xi \), labelling spherically symmetric foliations of the horizon, gives
\[ \frac{dr}{d\xi} = 2 \frac{\partial m}{\partial v} \frac{dv}{d\xi} + 2 \frac{\partial m}{\partial r} \frac{dr}{d\xi}. \] (37)
If we take $\xi = v$ and rearrange using the formula for the area $A = 4\pi r^2$ this becomes
\[
\frac{\partial m}{\partial v} = \frac{1}{8\pi} \frac{(1 - 2m')}{2r} \frac{\mathrm{d}A}{\mathrm{d}v},
\] (38)
where $m' = \frac{\partial m}{\partial r}$. In order for this to take the same form as the first law of black hole thermodynamics $\mathrm{d}m = \frac{1}{8\pi} \kappa \mathrm{d}A$ it seems natural to take
\[
\kappa_N = \frac{(1 - 2m')}{2r_H}.
\] (39)
This gives a natural normalization of the surface gravity in terms of the Misner–Sharp mass function, which we can interpret as the mass of the black hole contained within the radius $r_H$. In the static case, this does not reduce to the usual Killing horizon definition, although this derivation automatically assumes a dynamical evolution since, in the static case, the differentiation with respect to $v$ is not valid. It is also interesting to note that the direct differentiation of (36) gives
\[
\frac{\mathrm{d}m}{\mathrm{d}v} = \frac{1}{8\pi} \frac{1}{2r_H} \frac{\mathrm{d}A}{\mathrm{d}v},
\] (40)
suggesting a surface gravity identical to the one mentioned in [6] for a dynamical horizon in spherical symmetry.

4. Conclusion

We have seen a variety of ways of defining the surface gravity for dynamical situations and have computed the form of these variations in spherically symmetric spacetimes. The results seem to fall into three different categories. Firstly, there is the very simple form $\kappa = 1/2r_H$ [6], which was also briefly alluded to in [12]. The second category is of the form $\kappa = (1 - 2m')/2m$ (29), (33) and (39), while the third category is of the form $\kappa = A(1 - 2m')/4m + \dot{A}/A$ (25). Only the third form gives the correct Killing horizon behaviour in the static limit for spherically symmetric spacetimes, although all forms give the correct version for the Schwarzschild spacetime. However, the first and second categories seem to be much more closely related to full dynamical evolution of the horizon. In situations where one can set $A = 1$ everywhere, such as the Vaidya solution, the second and third categories will coincide.

It thus seems that the issue of the dynamical surface gravity is far from clear for general black holes. For the reasons stated in the introduction, a definition of the dynamical surface gravity is certainly needed. If one restricts to purely static spacetimes then one cannot really claim to be doing thermodynamics, only thermostatics. What role one wants the surface gravity to play depends on the context. In terms of the classical first law of black hole mechanics there is a close connection between the definition of the surface gravity and a choice of quasi-local mass. We have noted that using this approach there is a tension between the surface gravity defined in terms of a Killing horizon and the static limit of the surface gravity defined in terms of the Misner–Sharp quasi-local mass in a spherically symmetric spacetime. In spherical symmetry the Misner–Sharp mass is equivalent to the Hawking mass and forms a 'preferred' quasi-local mass. In rotating spacetimes, such as the Kerr solution, the Hawking mass may not give a useful definition of the mass associated with the horizon [6] and thus the situation is not as clear.

Furthermore, in spherical symmetry it is easy to show that the Hawking–Gibbons method for calculating the temperature of a static black hole (by eliminating the conical singularity in the Euclidean sector) gives a finite temperature for the Hawking radiation corresponding to the Killing horizon surface gravity (18). This is also true of the temperature computed from
the ‘tunnelling method’ for calculating the Hawking flux [8]. However, this version does not
correspond to the versions derived from a fully dynamical first law of black hole evolution.
Whether this apparent ‘tension’ between the two formulations has any deeper significance for
understanding the fully dynamical evolution of black holes remains to be seen.

Appendix. Double null foliations of the Schwarzschild metric

In [20] Mukohyama and Hayward define a double null foliation based on two foliations of
null hypersurfaces labelled by $\xi^+$ and $\xi^-$. In order to compare their notation with the notation
used here, in the following all tensors from Mukohyama and Hayward will have a $+$ or a $-$
attached to them. We will also use abstract index notation for consistency, although it is not
used by Mukohyama and Hayward. They define 1-forms normal to the null hypersurfaces by
$n^\pm_a = -\nabla_a \xi^\pm$. In abstract index notation this corresponds to

$$n^+_a = -\nabla_a \xi^+$$

(A.1)

and

$$n^-_a = -\nabla_a \xi^-.$$  

(A.2)

Since $d^2 \xi^\pm = 0$, both of these 1-forms are dual to affinely parametrized tangent vectors of
null geodesics. In terms of abstract index notation we have

$$\nabla_a n^\pm_b - \nabla_b n^\pm_a = 0,$$

(A.3)

contracting this with $g^{-1}(n_\pm)$ we have

$$n^{\pm a}(\nabla_a n^\pm_b - \nabla_b n^\pm_a) = 0$$

$$\Rightarrow n^{\pm a}\nabla_a n^\pm_b - \frac{1}{2}\nabla_b (n^{\pm a}n^\pm_a) = 0$$

$$\Rightarrow n^{\pm a}\nabla_a n^\pm_b = 0,$$

(A.4)

where the last two lines follow from the Leibniz rule, metric compatibility of the covariant
derivative and the fact that $n^{\pm a}n^\pm_a = 0$ everywhere. However, in general, we can choose both
null vectors to be non-affinely parametrized by making the choices

$$n_a = \Gamma n^+_a$$

(A.5)

and

$$l_a = \Lambda n^-_a,$$

(A.6)

where $1/\Gamma$ is a spacetime-dependent factor that makes $n^a$ affinely parametrized and $1/\Lambda$ is
a spacetime-dependent factor that makes $l^a$ affinely parametrized. In particular, in advanced
Eddington–Finkelstein coordinates $(v, r, \theta, \phi)$, the ingoing null geodesics are naturally affinely
parametrized ($\Gamma = 1$) and we can equate

$$n_a = n^+_a$$

(A.7)

and

$$l_a = \Lambda n^-_a.$$  

(A.8)
The 1-forms have components
\[ n_\mu = (-1, 0, 0, 0), \]  
\[ l_\mu = \left( -\frac{A^2 \Delta}{2}, A, 0, 0 \right). \]  
(A.9)  
(A.10)

The corresponding vector components are
\[ n^\mu = \left( 0, -\frac{1}{A}, 0, 0 \right), \]  
\[ l^\mu = \left( 1, \frac{A \Delta}{2}, 0, 0 \right). \]  
(A.11)  
(A.12)

In this form \( n^\mu \) is affinely parametrized while \( l^\mu \) is not and the conventional normalization has been chosen so that \( l^\mu n_\mu = -1 \).

Returning to the general case, we can choose the cross-normalization for \( l^\mu \) and \( n^\mu \) such that \( l^\mu n_\mu = -1 \). Since Mukohyama and Hayward have \( g^{-1} (n^*, n^-) = -e^f \) we see that
\[ e^f = \frac{1}{\Lambda \Gamma}. \]  
(A.13)

Now Mukohyama and Hayward define two null normal vectors by \( l_{\pm} = e^{-f} g^{-1} (n^\pm) \) (note the switch as \( \pm \) becomes \( \mp \)). In our notation this becomes
\[ l_+ = \Lambda \Gamma g^{ab} n_b = \Gamma l^a, \]  
\[ l_- = \Lambda \Gamma g^{ab} n_b = \Lambda n^a. \]  
(A.14)  
(A.15)

The expansions of \( l_{\pm} \) are defined by \( \theta_{\pm} = \ast L_{\pm} \ast 1 \) where \( L_{\pm} \) is the Lie derivative with respect to \( l_{\pm} \) and \( \ast \) is the Hodge dual operation associated with the projection of the metric onto a 2-sphere to which both \( l^a \) and \( l^- \) are normal. Using the anti-symmetric area 2-form, or Levi-Civita tensor for the 2-surface, \( \epsilon_{ab} \) this can be written as
\[ \theta_{\pm} = \frac{1}{2} \epsilon_{ab} L_{\pm} \epsilon_{ab} = 0. \]  
(A.16)

Thus we have
\[ \theta_- = \frac{1}{2} \epsilon_{ab} L_- \epsilon_{ab} \]  
\[ = \frac{\epsilon_{ab}}{2} \left( \nabla_c e_{ab} + \epsilon_{cb} \nabla_a l^b - \epsilon_{ac} \nabla_b l^c \right) \]  
\[ = \frac{\epsilon_{ab}}{2} \left( \Lambda n^c \nabla_c e_{ab} + \epsilon_{cb} \Lambda n^a \nabla_a n^c + \epsilon_{ac} \Lambda n^b \nabla_b n^c \right) \]  
\[ = \Lambda \frac{\epsilon_{ab}}{2} \nabla_n \epsilon_{ab}, \]  
(A.17)

where terms such as \( \epsilon_{cb} n^c \nabla_a A \) are zero because \( n^c \) is normal to the surface \( \epsilon_{cb} n^c = 0 \). Similarly we find \( \theta_+ = \frac{1}{2} \epsilon_{ab} L_+ \epsilon_{ab} \). The area 2-form can be given in terms of the Newman–Penrose null tetrad, as in Ashtekar et al [17], as
\[ \epsilon_{ab} = i (m_a \bar{m}_b - \bar{m}_a m_b). \]  
(A.18)
We can use this to calculate the expansions by

$$\frac{1}{2} e^{ab} L_n e_{ab} = - \frac{1}{2} (m^a \bar{m}^b - \bar{m}^a m^b) L_n (m_a \bar{m}_b - \bar{m}_a m_b).$$

(A.19)

Performing the necessary permutations, and using the fact that the expansion as given in (5) is equivalent to \((m^a \bar{m}^b + \bar{m}^a m^b) \nabla a b\), we find

$$\theta_\iota = \frac{\Lambda}{2} e^{ab} L_n e_{ab} = \Lambda (m^a \bar{m}^b + \bar{m}^a m^b) \nabla a n_b = \Lambda \theta_n$$

(A.20)

and similarly

$$\theta_\iota = \frac{\Gamma}{2} e^{ab} L_n e_{ab} = \Gamma (m^a \bar{m}^b + \bar{m}^a m^b) \nabla a l_b = \Gamma \theta_l.$$  

(A.21)

This gives

$$e^f (L_\iota \theta_\iota + L_\iota \theta_\iota + \theta_\iota \theta_\iota) = l^a \nabla_a \theta_\iota + n^a \nabla_a \theta_l + \frac{\theta_n}{\Lambda} l^a \nabla_a \Lambda + \frac{\theta_l}{\Gamma} n^a \nabla_a \Gamma + \theta_n \theta_l.$$  

(A.22)

The surface gravity of Mukohyama and Hayward, for a spherically symmetric trapping horizon, is

$$\kappa_M = - \frac{1}{16 \pi r} \int_S d^2 \theta \sqrt{h} \ e^f (L_\iota \theta_\iota + L_\iota \theta_\iota + \theta_\iota \theta_\iota)$$

$$= - \frac{r}{4} \left( l^a \nabla_a \theta_\iota + n^a \nabla_a \theta_l + \frac{\theta_n}{\Lambda} l^a \nabla_a \Lambda \right).$$

(A.23)

In order to use this definition we need to know what the factor \(\Lambda\) is that makes \(l^a\) affinely parametrized. To do this we need to pick a coordinate system that is regular on the horizon. It is difficult, at least in advanced Eddington–Finkelstein coordinates, to calculate what the affine parameter for the outgoing null vectors should be. By examining the way the surface gravity changes under a reparametrization of \(l^a\) we see that for a non-affine parametrization we have

$$l^a \nabla_a \Lambda = - \Lambda n^a l^b \nabla_b l_a.$$  

(A.24)

Using the non-affine parametrization given above, (22) and (23), this becomes

$$\partial_\iota (\Lambda) + \frac{A \Delta}{2} \partial_\iota (A) = \Lambda \left( \frac{\dot{A}}{A} + A' \Delta + \frac{\Delta'}{2} \right)$$

(A.25)

or

$$\partial_\iota (\ln \Lambda) + \frac{A \Delta}{2} \partial_\iota (\ln A) = \frac{\dot{A}}{A} + A' \Delta + \frac{\Delta'}{2}.$$  

(A.26)

The solution of this first-order partial differential equation will depend on the specific situation. For static solutions we have \(\dot{A} = 0 = \partial_\iota (\ln \Lambda)\) and the solution to the ordinary differential equation is just

$$\Lambda = k A^2 \Delta,$$

(A.27)

where \(k\) is a constant of integration. Therefore, for the static case we have \(l^a \nabla_a \theta_\iota = 0\), \(n^a \nabla_a \theta_\iota = - \Delta' / r\), \(\theta_\iota = -2 / (\Lambda r)\) and

$$\kappa_M = - \frac{1}{4M} (1 - 2m'),$$

(A.28)

which we see will match the Killing horizon value for \(A = 1\). In particular, in the static Schwarzschild solution \(\Lambda = \Delta\) and we have, at the horizon \(\Delta = 0\),

$$n^a \nabla_a \theta_l = - \frac{2M}{r^3}.$$  

(A.29)
In Kruskal–Szekerés coordinates \((T, R, \theta, \phi)\) we can easily generate a double null foliation and thus find affinely parametrized null normals. The Schwarzschild solution takes the form

\[
\text{ds}^2 = -\frac{32M^3}{r} e^{-r/2M} (-dT^2 + dR^2) + r^2 d\Omega^2.
\]  
(A.33)

This can be written in double null coordinates by identifying

\[
v = T + R, \quad u = T - R.
\]  
(A.34)
(A.35)

In double null coordinates \((u, v, \theta, \phi)\) the Schwarzschild metric takes the form

\[
\text{ds}^2 = -\frac{32M^3}{r} e^{-r/2M} du dv + r^2 d\Omega^2.
\]  
(A.36)

The radial null vectors are

\[
l^\mu = \left(0, \frac{r}{16M^3} e^{r/2M}, 0, 0\right),
\]  
(A.37)
 \[
l_\mu = (-1, 0, 0, 0),
\]  
(A.38)

and

\[
n^\mu = \left(\frac{r}{16M^3} e^{r/2M}, 0, 0, 0\right),
\]  
(A.39)
 \[
n_\mu = (0, -1, 0, 0).
\]  
(A.40)

For these choices we have \(l^\mu l_\mu = 0 = n^\mu n_\mu\) and

\[
l^\mu n_\mu = -\frac{r}{16M^3} e^{r/2M}.
\]  
(A.41)

Thus, if we take \(l^\mu\) to be \(l^+\) and \(n^\mu\) to be \(n^-\), in terms of Mukohyama and Hayward’s notation, we have

\[
e^f = \frac{r}{16M^3} e^{r/2M},
\]  
(A.42)
 \[
\theta_+ = \frac{e^{r/2M} \partial_+ r}{8M^3},
\]  
(A.43)
 \[
\theta_- = \frac{e^{r/2M} \partial_- r}{8M^3},
\]  
(A.44)
 \[
e^f \mathcal{L}_- \theta_+ = -\frac{e^{r/2M} \partial_- r \partial_+ r - r \partial_+ \partial_- r}{8M^3 r},
\]  
(A.45)
 \[
e^f \mathcal{L}_+ \theta_- = -\frac{e^{r/2M} \partial_+ r \partial_- r - r \partial_- \partial_+ r}{8M^3 r}.
\]  
(A.46)
The surface gravity for the horizon is now simply given by
\[
\kappa_M = -\frac{r}{4} e^{f} (\mathcal{L}_- \theta_+ + \mathcal{L}_+ \theta_-).
\] (A.47)

Since we can write the double null coordinates \(u, v\) in terms of Schwarzschild coordinates \(r, t\) as
\[
v = \sqrt{\frac{r}{2M} - \frac{1}{4} e^{(r+t)/4M}},
\] (A.48)
\[
u = -\sqrt{\frac{r}{2M} - \frac{1}{4} e^{(r-t)/4M}},
\] (A.49)
we have
\[
uv = \left(1 - \frac{r}{2M}\right) e^{r/2M}
\] (A.50)
and thus, at the horizon \(r = 2M\),
\[
\partial_u \partial_v r = -2M.
\] (A.51)
Putting it all together with \(\theta_+ = 0\) gives
\[
\kappa_M = \frac{1}{4M}.
\] (A.52)
This value agrees with the value given by the Killing horizon method for the Schwarzschild solution.
