Abstract

Genome-wide accurate identification and quantification of full-length mRNA isoforms is crucial for investigating transcriptional and post-transcriptional regulatory mechanisms of biological phenomena. Despite continuing efforts in developing effective computational tools to identify or assemble full-length mRNA isoforms from next-generation RNA-seq data, it remains a challenge to accurately identify mRNA isoforms from short sequence reads due to the substantial information loss in RNA-seq experiments. Here we introduce a novel statistical method, AIDE (Annotation-assisted Isoform Discovery and abundance Estimation), the first approach that directly controls false isoform discoveries by implementing the statistical model selection principle. Solving the isoform discovery problem in a stepwise and conservative manner, AIDE prioritizes the annotated isoforms and precisely identifies novel isoforms whose addition significantly improves the explanation of observed RNA-seq reads. We evaluate the performance of AIDE based on multiple simulated and real RNA-seq datasets followed by a PCR-Sanger sequencing validation. Our results show that AIDE effectively leverages the annotation information to compensate the information loss due to short read lengths. AIDE achieves the highest precision in isoform discovery and the lowest error rates in isoform abundance estimation, compared with three state-of-the-art methods Cufflinks, SLIDE, and StringTie. As a robust bioinformatics tool for transcriptome analysis, AIDE will enable researchers to discover novel transcripts with high confidence.

Introduction

A transcriptome refers to the entire set of RNA molecules in a biological sample (e.g., a cell or a tissue sample). Alternative splicing, a post-transcriptional process during which particular exons
of a gene may be included into or excluded from a mature messenger RNA (mRNA) isoform (i.e., transcript) transcribed from that gene, is a key contributor to the diversity of eukaryotic transcriptomes [1]. Alternative splicing is a prevalent phenomenon in multicellular organisms, and it affects approximately 90%-95% of genes in mammals [2]. Understanding the diversity of eukaryotic transcriptomes is essential to interpreting gene functions and activities under different biological conditions [3]. In transcriptome analysis, a key task is to accurately identify the set of existing isoforms and estimate their abundance levels under a specific biological condition, because the information on isoform composition is critical to understanding the isoform-level dynamics of RNA contents in different cells, tissues, and developmental stages. Abnormal splicing events have been known to cause many genetic disorders [4], such as retinitis pigmentosa [5] and spinal muscular atrophy [6]. Accurate isoform identification and quantification will shed light on gene regulatory mechanisms of genetic diseases, thus assisting biomedical researchers in designing targeted therapies for diseases.

The identification of truly expressed isoforms is an indispensable step preceding accurate isoform quantification. However, compared with the quantification task, isoform discovery is an inherently more challenging problem both theoretically and computationally. The reasons behind this challenge are threefold. First, next-generation RNA-seq reads are too short compared with full-length mRNA isoforms. RNA-seq reads are typically no longer than 300 base pairs (bp) in Illumina sequencing [7], while more than 95% of human isoforms are longer than 300 bp, with a mean length of 1,712 bp (the GENCODE annotation, Release 24) [8]. Hence, RNA-seq reads are short fragments of full-length mRNA isoforms. Due to the fact that most isoforms of the same gene share some overlapping regions, many RNA-seq reads do not unequivocally map to a unique isoform. As a result, isoform origins of those reads are ambiguous and need to be inferred from a huge pool of candidate isoforms. Another consequence of short reads is that “junction reads” spanning more than one exon-exon junctions are underrepresented in next-generation RNA-seq data, due to the difficulty of mapping junction reads (every read needs to be split into at least two segments and has all the segments mapped to different exons in the reference genome). The underrepresentation of those junction reads further increases the difficulty of discovering full-length RNA isoforms accurately. Second, the number of candidate isoforms increases exponentially with the number of exons. Hence, computational efficiency becomes an inevitable factor that every computational method must account for, and an effective isoform screening step is often needed to achieve accurate isoform discovery [9]. Third, it is a known biological phenomenon that often only a small number of isoforms are truly expressed under one biological condition. Given the huge number of candidate isoforms, how isoform discovery methods balance the parsimony and the accuracy of their discovered isoforms becomes a critical and meanwhile difficult issue [10, 11]. For more comprehensive discussion and comparison of existing isoform discovery methods, readers can refer to [12] and [13].

Over the past eight years, computational researchers have developed multiple state-of-the-art isoform discovery methods to tackle one or more of the challenges mentioned above. The two
earliest annotation-free methods are Cufflinks [14] and Scripture [15], which can assemble mRNA isoforms solely from RNA-seq data without using annotations of known isoforms. Both methods use graph-based approaches, but they differ in how they construct graphs and then parse a graph into isoforms. Scripture first constructs a connectivity graph with nodes as genomic positions and edges determined by junction reads. It then scans the graph with fixed-sized windows, scores each path for significance, connects the significant paths into candidate isoforms, and finally refines the isoforms using paired-end reads. Cufflinks constructs an overlap graph of mapped reads, and it puts a directed edge based on the genome orientation between two compatible reads that could arise from the same isoform. It then finds a minimal set of paths that cover all the fragments in the overlap graph. A more recent method StringTie also uses the graph idea. It first creates a splice graph with read clusters as nodes to identify isoforms, and it then constructs a flow network to estimate the expression levels of isoforms using a maximum flow algorithm [16].

Another suite of methods utilize different statistical and computational tools and regularization methods to tackle the problems of isoform discovery and abundance estimation. IsoLasso [17], SLIDE [18], and CIDANE [10] all build linear models, where read counts are summarized as the response variable, and isoform abundances are treated as parameters to be estimated. The candidate isoforms with non-zero estimated abundance are then considered as discovered. IsoLasso starts from enumerating valid isoforms and then uses the Lasso algorithm [19] to achieve parsimony in its discovered isoforms. SLIDE incorporates the information of gene and exon boundaries in annotations to enumerate candidate isoforms, and it uses a modified Lasso procedure to select isoforms. CIDANE also uses the Lasso regression in its first phase, and then it employs a delayed column generation technique in its second phase to check if new isoforms should be added to improve the solution. Another method iReckon takes a different approach and tackles the isoform discovery problem via maximum likelihood estimation [11]. It first constructs all the candidate isoforms supported by RNA-seq data, and then it utilizes a regularized expectation-maximization (EM) algorithm [20] to reduce the number of expressed isoforms and avoid over-fitting.

Aside from the intrinsic difficulty of isoform identification due to the short read lengths and the huge number of candidate isoforms, the excess biases in RNA-seq experiments further afflict the isoform discovery problem. Ideally, RNA-seq reads are expected to be uniformly distributed within each isoform. However, the observed distribution of RNA-seq reads significantly violates the uniformity assumption due to multiple sources of biases. The most commonly acknowledged bias source is the different levels of guanine-cytosine contents (GC contents) in different regions of an isoform. The GC content bias was first investigated by Dohm et al. [21], and a significantly positive correlation was observed between the read coverage and the GC contents. Another work later showed that the effects of GC contents tend to be sample-specific [22]. Another major bias source is the positional bias, which causes the uneven read coverage at different relative positions within an isoform. As a result of the positional bias, reads are more likely to be generated from certain regions of an isoform, depending on experimental protocols, e.g., whether cDNA fragmentation or RNA fragmentation is used [23, 24]. Failing to correct these biases will likely lead to high false
discovery rates in isoform discovery and unreliable statistical results in downstream analyses e.g.,
differential isoform expression analysis [25].

Current computational methods account for the non-uniformity of reads using three main ap-
proaches: to adjust read counts summarized in defined genomic regions to offset the non-uniformity
bias [23, 26], to assign a weight to each single read to adjust for bias [27], and to incorporate the
bias as a model parameter in likelihood-based methods [28, 29, 30, 31] for isoform discovery or
abundance estimation.

Despite continuous efforts the bioinformatics community has spent on developing effective
computational methods to identify full-length isoforms from next-generation RNA-seq data, the
existing methods still suffer from low accuracy for genes with complex splicing structures [12, 32].
A comprehensive assessment has shown that methods achieving good accuracy in identifying iso-
forms in *D. melanogaster* (34, 776 annotated isoforms) and *C. elegans* (61, 109 annotated isoforms)
fail to maintain good performance in *H. sapiens* (200, 310 annotated isoforms) [12, 33]. Although
it is generally believed that deeper sequencing will lead to better isoform discovery results, the
improvement is not significant in *H. sapiens*, compared with *D. melanogaster* and *C. elegans*, due
to the complex splicing structures of human genes [34, 12]. Moreover, despite increasing precision
and recall rates of identified isoforms evaluated at the nucleotide level and the exon level, it remains
challenging to improve the isoform-level performance. In other words, even when all sub-isoform
elements (i.e., short components of transcribed regions such as exons) are correctly identified,
accurate assembly of these elements into full length isoforms remains a big challenge.

Motivated by the observed low accuracy in identifying full-length isoforms solely from RNA-
seq data, researchers have considered leveraging information from reference annotations (e.g.,
ENSEMBL [33], GENCODE [8], and UCSC Genome Browser [35]) to aid isoform discovery.
Existing efforts include two approaches. In the first approach, methods extract the coordinates
of gene and exon boundaries, i.e., known splicing sites, from annotations and then assemble
novel isoforms based on the exons or subexons (the regions between adjacent known splicing
sites) of every gene [10, 16, 18]. In the second approach, methods directly incorporate all the
isoforms in annotations by simulating faux-reads from the annotated isoforms [36]. However, the
above two approaches have strong limitations in their use of annotations. The first approach
does not fully use annotation information because it neglects the splicing patterns of annotated
isoforms, and these patterns could assist learning the relationship between short reads and full-
length isoforms. The second approach is unable to filter out non-expressed annotated isoforms
because researchers lack prior knowledge on which annotated isoforms are expressed in an RNA-
seq sample; hence, its addition of unnecessary faux-reads will bias the isoform discovery results
and lose control of the false discovery rate.

Here we propose a more statistically principled approach, AIDE (Annotation-assisted Isoform
Discovery and abundance Estimation), to leverage annotation information in a more advanced
manner to increase the precision and robustness of isoform discovery. Our approach is rooted in
statistical model selection, which takes a conservative perspective to search for the smallest model
that fits the data well, after adjusting for the model complexity. In our context, a model corresponds to a set of candidate isoforms (including annotated ones and novel ones), and a more complex model contains more isoforms. Our rationale is that a robust and conservative computational method should only consider novel isoforms as credible if adding them would significantly better explain the observed RNA-seq reads than using only the annotated isoforms. AIDE differs from many existing approaches in that it does not aim to find all seemingly novel isoforms. It enables controlling false discoveries in isoform identification by employing a statistical testing procedure, which ensures that the discovered isoforms make statistically significant contributions to explaining the observed RNA-seq reads. Specifically, AIDE learns gene and exon boundaries from annotations and also selectively borrows information from the annotated isoform structures using a stepwise likelihood-based selection approach. Instead of fully relying on the annotation, AIDE is capable of identifying non-expressed annotated isoforms and remove them from the identified isoform set. Moreover, AIDE simultaneously estimates the abundance of the identified isoforms in the process of isoform reconstruction.

Results

The AIDE method utilizes the likelihood ratio test to identify isoforms via a stepwise selection procedure, which gives priority to the annotated isoforms and selectively borrows information from their structures. The stepwise selection in AIDE consists of both forward and backward steps. Each forward step finds an isoform whose addition contributes the most to the explanation of RNA-seq reads given the currently identified isoforms. Each backward step rectifies the identified isoform set by removing the isoform with the most trivial contribution given other identified isoforms. AIDE achieves simultaneous isoform discovery and abundance estimation based on a carefully constructed probabilistic model of RNA-seq read generation, and the stepwise selection process consists of model parameter estimation and likelihood ratio tests (see Methods; Figure 1). We first used a comprehensive transcriptome-wide study to evaluate and compare the performance of AIDE and three other widely used methods (Cufflinks, SLIDE, and StringTie) provided with various read coverages and annotations of different quality. Second, we validated the isoform discovery results of these four methods using a benchmark Nanostring dataset. Third, we further assessed the precision and recall rates of these four methods on human and mouse RNA-seq datasets. We finally used a simulation study to demonstrate the necessity and superiority of stepwise selection in AIDE. In all the above four studies, AIDE demonstrated its advantages in achieving the highest precision in isoform discovery and the best accuracy in isoform quantification among the four methods.
Initialization: the annotated isoform with the most compatible reads

**Forward Step**
- select one isoform using MLE; p value ≥ threshold in the LRT?
  - Yes; add the selected isoform to the identified set
  - No; go to stage 2

**Backward Step**
- select one isoform using MLE; p value > threshold in the LRT?
  - Yes; remove the selected isoform from the identified set
  - No; go to forward

**Stage 1**
- consider annotation only

**Stage 2**
- consider all the possible isoforms

**Initialization:** selected annotated isoform(s)

**Forward Step**
- select one isoform using MLE; p value ≥ threshold in the LRT?
  - Yes; add the selected isoform to the identified set
  - No; go to stage 2

**Backward Step**
- select one isoform using MLE; p value > threshold in the LRT?
  - Yes; remove the selected isoform from the identified set
  - No; go to forward

**Stop**

Figure 1: Workflow of the stepwise selection in the AIDE method. Stage 1 starts with a single annotated isoform compatible with the most reads, and all the other annotated isoforms are considered as candidate isoforms. Stage 2 starts with the annotated isoforms selected in stage 1, and all the possible isoforms, including the unselected annotated isoforms, are considered as candidate isoforms. In the forward step in both stages, AIDE identifies the isoform that mostly increases the likelihood, and it uses the likelihood ratio test (LRT) to decide whether this increase is statistically significant. If significant, AIDE adds this isoform to its identified isoform set; otherwise, AIDE keeps its identified set and terminates the current stage. In the backward step in both stages, AIDE finds the isoform in its identified set such that the removal of this isoform decreases the likelihood the least, and it uses the likelihood ratio test to decide whether this decrease is statistically significant. If significant, AIDE removes this isoform from its identified set; otherwise, AIDE keeps the identified set. After the backward step, AIDE returns to the forward step. AIDE stops when the forward step in Stage 2 no longer adds a candidate isoform to the identified set.

AIDE outperforms state-of-the-art methods on simulated data

We compared AIDE with three other state-of-the-art isoform discovery methods, Cufflinks [14], StringTie [16], and SLIDE [18], in a simulation setting that well mimicked real RNA-seq data analysis. The four methods tackle the isoform discovery task from different perspectives. Cufflinks assembles isoforms by constructing an overlap graph and searching for isoforms as sparse paths in the graph, and is currently the most highly cited method for isoform reconstruction. SLIDE utilizes a regularized linear model, and demonstrated precise results in large-scale comparisons [12]. StringTie uses a network-based algorithm, and achieves the best computational efficiency and memory usage among the existing methods [16]. Unlike all these three methods, our proposed method AIDE, built upon likelihood ratio tests and stepwise selection, converts the isoform discovery problem into a statistical variable selection problem.

To conduct a fair assessment of the four methods, we simulated RNA-seq datasets using the R package polyester [24], which uses both built-in models and real RNA-seq datasets to generate synthetic RNA-seq data that exhibit similar properties to those of real data. We simulated eight human RNA-seq datasets with eight different read coverages (10x, 20x, ..., 80x) and pre-
determined isoform fractions (see Methods). An \( n \times \) coverage means that an exonic genomic locus is covered by \( n \) reads on average. We compared the accuracy of the four methods supplied with annotations of different quality. In real scenarios, annotations contain both expressed (true) and non-expressed (false) isoforms in a specific RNA-seq sample. Annotations might miss some expressed isoforms in that RNA-seq sample because alternative splicing is known to be condition-specific and widely diverse across different conditions. Therefore, it is critical to evaluate the extent to which different methods rely on the accuracy of annotations, specifically the annotation purity and the annotation completeness, which we define as the proportion of expressed isoforms among the annotated ones and the proportion of annotated isoforms among the expressed ones, respectively.

We constructed nine sets of synthetic annotations (as opposed to the real annotation from GENCODE [8] or Ensembl [37]), with varying purity and completeness (Table 1). For example, annotation 4 has a 60% purity and a 40% completeness, meaning that 60% of the annotated isoforms are truly expressed and the annotated isoforms constitute 40% of the truly expressed isoforms.

**Table 1:** Synthetic annotations. Purity and completeness of the nine sets of synthetic annotations are calculated based on the truly expressed isoforms in the simulated data.

| synthetic annotation set | purity | 1   | 2   | 3   | 4   | 5   | 6   | 7   | 8   | 9   |
|--------------------------|--------|-----|-----|-----|-----|-----|-----|-----|-----|-----|
|                          |        | 40% | 40% | 40% | 60% | 60% | 60% | 60% | 80% | 80% |
|                          |        | 40% | 60% | 80% | 40% | 60% | 80% | 40% | 60% | 80% |

We first compared AIDE and the other three methods Cufflinks, SLIDE, and StringTie in terms of their isoform discovery accuracy per gene. Regarding both the precision rates (i.e., the proportions of expressed isoforms in the discovered isoforms) and the recall rates (i.e., the proportions of discovered isoforms in the expressed isoforms), AIDE outperforms the other three methods with all the nine sets of synthetic annotations (Figures 2, S2, and S3). Especially with the less accurate synthetic annotation sets 1-4, AIDE demonstrates its clear advantages in precision and recall rates thanks to its stepwise selection strategy, which prevents AIDE from being misled by the wrongly annotated isoforms. When the read coverage is 10x and the annotations have 40% purity (sets 1-3), the median precision rates of AIDE are as high as the 3rd-quantile precision rates of Cufflinks. In addition, AIDE achieves high precision rates (> 75%) much more frequently than the other three methods (Figure 2a). In terms of the recall rates, AIDE and Cufflinks exhibit better capability in correctly identifying truly expressed isoforms than StringTie and SLIDE. AIDE achieves high recall rates (> 75%) in more genes with the annotation sets 1-3 (purity = 40%), and its recall rates are close to those of Cufflinks when the annotation purity is increased to 60% and 80% (annotation sets 4-9) (Figure 2b). We also find that AIDE is robust to sequencing depths. On the contrary, the recall rates of StringTie and SLIDE deteriorate quickly as sequencing depths decrease (Figures S2 and S3). Regarding to what extent does the accuracy of annotations affect isoform discovery, we find that the annotation purity is more important than
the annotation completeness for isoform discovery (Figures 2, S2, and S3). This observation suggests that if practitioners have to choose between two annotation sets, one with high purity but low completeness and the other with low purity but high completeness, they should use the former annotation set as input into AIDE.

As a concrete example, we considered the human gene DPM1 and its annotated isoforms in synthetic annotation sets 1 and 9 (Table 1). For DPM1, the annotation set 1 has a 67% purity and a 67% completeness, and the annotation set 9 has a 60% purity and a 100% completeness. In Figures S4 and S5, we plotted the distribution of RNA-seq reads in the reference genome, along with the truly expressed isoforms, the annotated isoforms, and the isoforms identified by AIDE, Cufflinks, and StringTie, respectively. Thanks to its capacity to selectively incorporate information from the annotated isoforms, AIDE successfully identified the shortest truly expressed isoform, which is missing in the annotation set 1 (Figure S4). With the annotation set 9 that contains two non-expressed isoforms, AIDE correctly identified the three truly expressed isoforms (Figure S5).
In contrast, Cufflinks, StringTie, and SLIDE missed some of the truly expressed isoforms with both annotation sets. Specifically, they missed the shortest expressed isoform not in the annotation set 1, and they identified too many non-expressed isoforms with the less pure annotation set 9.

![Graph showing precision and recall curves for different annotation sets.](image)

**Figure 3:** Comparison between AIDE and the other three isoform discovery methods in simulation. Given each synthetic annotation set, we applied AIDE, Cufflinks, StringTie, and SLIDE for isoform discovery, and summarized the expression levels of the predicted isoforms using the FPKM (Fragments Per Kilobase Million) unit. Then the precision-recall curves were obtained by thresholding the FPKM values of the predicted isoforms. These precision and recall rates are average across human genes. The AUC of each method is also marked in the plot. The shown results are based on RNA-seq data with a 10x coverage.

We also summarized the genome-wide average precision rates, recall rates, and $F$ scores of AIDE and the other three methods at three different levels: base, exon and isoform levels, with each of the nine synthetic annotation sets (Figure S6). Please see Supplementary Materials for the definitions of the precision rate, the recall rate, and the $F$ score at the base, exon, and isoform levels. All the four methods have high accuracy at the base and exon levels regardless of the accuracy of the synthetic annotations. However, even when exons are correctly identified, it remains challenging to accurately assemble exons into full-length isoforms. At the isoform level, AIDE achieves the best precision rates, recall rates comparable to Cufflinks, and the best $F$ scores with all the synthetic annotation sets. In addition to the reconstruction accuracy based on the
initial output of each method, we also compared the precision-recall curves of different methods by applying varying thresholds on the calculated isoform expression levels (Figure 3). Regardless of the annotation quality, AIDE achieves higher precision rate than the other three methods when all the methods lead to the same recall rate. It is worth noting that the results of AIDE were filtered by statistical significance before thresholded by expression values, while the results of the other three methods were only thresholded by isoform expression. Therefore, it is not fair to directly compare the maximum recall rates or AUC (area under the curve) scores of different methods. Nonetheless, AIDE still has the largest AUC scores. These results demonstrate the advantage of AIDE in achieving high precision and low false discovery rates in isoform discovery.

As for every gene, the proportions of the expressed isoforms were specified in this simulation study, we also compared AIDE with the other three methods in terms of their accuracy in isoform abundance estimation. We use $\alpha = (\alpha_1, \ldots, \alpha_J)'$ to denote the proportions of $J$ possible isoforms enumerated from a given gene’s known exons, and we use $\hat{\alpha} = (\hat{\alpha}_1, \ldots, \hat{\alpha}_J)'$ to denote the estimated proportions by a method. We note that $\sum_{j=1}^{J} \alpha_j = \sum_{j=1}^{J} \hat{\alpha}_j = 1$. We define the estimation error rate as the total variation: $e(\hat{\alpha}) = \frac{1}{2} \sum_{j=1}^{J} |\alpha_j - \hat{\alpha}_j|$. The error rate is a real value in $[0, 1]$, with a value 0 representing a 100% accuracy. With all the nine synthetic annotation sets, AIDE achieves the overall smallest error rates (Figure 2c). The advantages of AIDE over the other three methods are especially obvious with the first three annotations, whose purity is only 40%.

### AIDE improves isoform discovery on real data

We have demonstrated that AIDE achieves more precise isoform discovery and more accurate isoform abundance estimation than Cufflinks, StringTie, and SLIDE in simulations and on real data with Nanostring counts as a benchmark. In addition to these results, we performed another transcriptome-wide comparison of AIDE and the other three methods to further validate the robustness and reproducibility of AIDE in isoform discovery. Since transcriptome-wide benchmark data are unavailable for real RNA-seq experiments, we used the isoforms in the GENCODE annotation as a surrogate basis for evaluation [8]. For every gene, we randomly selected half of the annotated isoforms and input them as partial annotations into every isoform discovery method. For RNA-seq data, we collected from public data repository three human embryonic stem cell (ESC) datasets and three mouse bone marrow-derived macrophage datasets (Supplementary Table S1). For the human ESC data we used the GENCODE annotation version 24; for the mouse macrophage data we used the GENCODE annotation version 10. For each gene, we applied AIDE, Cufflinks, StringTie, and SLIDE to these six datasets for isoform discovery with partial annotations, and we evaluated the precision and recall rates of each method by comparing their identified isoforms with the complete set of annotated isoforms. Although the annotated isoforms are not equivalent to the truly expressed isoforms in the six samples from which RNA-seq data were generated, the identified isoforms, if accurate, are supposed to largely overlap with the annotated isoforms given the quality of human and mouse annotations. Especially if we assume the human and
mouse annotations are unions of known isoforms expressed under various well-studied biological conditions including human ESCs and mouse bone marrow-derived macrophages, it is reasonable to use those annotations to estimate the precision rates of the discovered isoforms, i.e., what proportions of the discovered isoforms are expressed. Estimation of the recall rates is more difficult, because the annotations are likely to include some isoforms that are non-expressed in human ESCs or mouse bone marrow-derived macrophages.

![Graphs showing comparison of methods for isoform discovery accuracy](image)

**Figure 4:** Comparison of AIDE and the other three methods in real data. **a:** exon-level accuracy in the human ESC samples; **b:** exon-level accuracy in the mouse macrophage samples; **c:** transcript-level accuracy in the human ESC samples; **d:** transcript-level accuracy in the mouse macrophage samples. The gray contours denote the $F$ scores, as marked on the right of each panel.

We summarized the isoform discovery accuracy of the four methods on each dataset at both the exon level and the isoform level in Figure 4. At the exon level, AIDE has the highest precision and recall rates on all the six datasets, achieving $F$ scores greater than 90% (Figure 4a-b). The second best method at the exon level is StringTie. Since connecting exons into the full-length isoforms is much more challenging than simply identifying the individual exons, all the methods have lower accuracy at the isoform level than at the exon level. While having slightly lower but similar recall rates than Cufflinks, AIDE achieves the highest precision rates ($\sim 70\%$ on human datasets and $\sim 60\%$ on mouse datasets) at the isoform level (Figure 4c-d). Moreover, when all the methods achieve the same recall rates after thresholding the estimated isoform expression levels (in FPKM unit), AIDE has the largest precision rate in all the six samples (Figure S7). Although precision and recall rates are both important measures for isoform discovery, high
precision results (equivalently, low false discovery results) of computational methods are often preferable for experimental validation. In the three mouse macrophage samples, AIDE identified novel isoforms for genes \textit{MAPKAPK2}, \textit{CXCL16}, and \textit{HIVEP1}, which are known to play important roles in macrophage activation [38, 39, 40]. Since AIDE has higher precision rates than the other three methods, these novel isoforms found by AIDE are worth investigating in macrophage studies.

In our previous simulation results, we have shown that the accuracy of annotations is a critical factor determining the performance of AIDE. Even though the partial annotations used in this study only have a 50% completeness, AIDE achieves the best precision rates among the four methods, and we expect AIDE to achieve high accuracy when supplied with annotations of better quality in real applications.

AIDE is able to achieve more precise isoform discovery than existing methods because it utilizes a statistical model selection principle to determine whether to identify a candidate isoform as expressed. Therefore, only those isoforms that are statistically supported by the evidence (i.e., the observed reads) are retained. We used four example genes \textit{ZBTB11}, \textit{TOR1A}, \textit{MALSU1}, and \textit{SRF6} to illustrate the superiority of AIDE over the other three methods (Supplementary Figures S8 and S9). The genome browser plots clearly show that AIDE identifies the annotated isoforms with the best precision, while the other methods either miss some annotated isoforms or lead to too many false discoveries. We also used the same genes \textit{ZBTB11}, \textit{TOR1A}, \textit{MALSU1}, and \textit{SRF6} to show that AIDE is robust to the choice of the $p$-value threshold used in the likelihood ratio tests (see Methods). The default choice of the threshold is $\frac{0.01}{\text{total number of genes}}$, which is $4.93 \times 10^{-7}$ for human samples and $4.54 \times 10^{-7}$ for mouse samples. We used AIDE to identify isoforms with different thresholds chosen from \{10$^{-2}$, 10$^{-3}$, 10$^{-4}$, 10$^{-5}$, 10$^{-6}$, 10$^{-7}$, 10$^{-8}$, 10$^{-9}$, 10$^{-10}$\} and tracked how the results change while the threshold decreases from 10$^{-2}$ to 10$^{-10}$ (Supplementary Figures S10 and S11). As expected, AIDE tends to discover slightly more isoforms when the threshold is larger, and it becomes more conservative with a smaller threshold. However, the default threshold leads to accurate results for those four genes, and the discovered isoform set remains stable around the default threshold.

**AIDE achieves the best consistency with long-read sequencing technologies**

We conducted another transcriptome-wide study to evaluate the above isoform discovery methods by comparing their reconstructed isoforms (from the next-generation, a.k.a, second-generation, short RNA-seq reads) to those identified by the third-generation long-read sequencing technologies, including Pacific Biosciences (PacBio) [41] and Oxford Nanopore Technologies (ONT) [42]. Even though PacBio and ONT platforms have higher sequencing error rates and lower throughputs compared to next-generation sequencing technologies, they are able to generate much longer reads (1-100kb) to simultaneously capture multiple splicing junctions [43]. Here we used the full-length transcripts identified from the PacBio or ONT sequencing data as a “surrogate gold standard” to evaluate the above isoform discovery methods.

We applied AIDE, Cufflinks, and StringTie to a next-generation RNA-seq sample of human
embryonic stem cells (hESCs), and compared their identified isoforms with those discovered from PacBio or ONT data generated from the same hESCs sample [43]. SLIDE requires its input RNA-seq reads to have the same mapped read length and is thus not applicable to this hESCs dataset. The comparison results based on ONT and PacBio are highly consistent: AIDE achieves the best precision and the highest overall accuracy ($F$ score) at both the base level and the transcript level (Figure 5). The fact that all the three methods have high accuracy at the exon level but much lower accuracy at the transcript level again indicate the difficulty of assembling exons into full-length isoforms based on short RNA-seq reads. Among all the three methods, AIDE is advantageous in achieving the best precision in full-length isoform discovery.

**PCR-Sanger sequencing validates the effective reduction of false discoveries by AIDE**

Since AIDE and Cufflinks have demonstrated higher accuracy than other methods in the assessment of genome-wide isoform discovery from synthetic and real RNA-seq datasets, we further evaluated the performance of these two methods on a small cohort of RNA-seq datasets using PCR followed by Sanger sequencing. We applied both AIDE and Cufflinks to five breast cancer RNA-seq datasets for isoform identification with GENCODE annotation version 24. After summarizing and comparing the genome-wide isoform discovery results, we randomly selected ten genes that have annotated transcripts uniquely predicted by only AIDE or Cufflinks with FPKM $> 2$ for experimental validation (Table S2). We summarized the genes into two categories: six genes with annotated isoforms identified only by Cufflinks but not by AIDE (category 1), and four genes with
annotated isoforms identified only by AIDE but not by Cufflinks (category 2). For four out of the six genes in category 1, MTHFD2, NPC2, RBM7, and CD164, our experimental validation found that the isoforms uniquely predicted by Cufflinks were false positives (Figure 6a-d). Specifically, both AIDE and Cufflinks correctly identified the full-length isoforms MTHFD2-201, NPC2-207, RBM7-203, CD164-003 for the four genes, respectively. However, the isoforms MTHFD2-203, NPC2-205, RBM7-208, CD164-210 predicted only by Cufflinks were all false discoveries. The validation results of category 1 indicates the potential of AIDE to effectively reduce false positive prediction of full-length mRNA isoforms compared with Cufflinks. For two out of the four genes in category 2, we validated the isoforms uniquely predicted by AIDE as true positives (Figure 6e-f). In detail, AIDE correctly identified isoforms FGFR1-238 and FGFR1-201 for gene FGFR1, as well as isoform ZFAND5-208 for gene ZFAND5. On the other hand, Cufflinks only identified FGFR1-201 and missed the other two isoforms. The validation results of category 2 suggests that AIDE also has good recall performance for isoform discovery in this case study.

AIDE identifies isoforms with biological relevance

We investigated the biological functions of FGFR1-238, an isoform predicted by AIDE but not by Cufflinks. Since FGFR1-238 was identified in breast cancer RNA-seq samples, we evaluated its functions in breast cancer development by a loss-of-function assay. In detail, we validated the expression of FGFR1-238 in breast cancer cell lines MCF7, BT549, SUM149, MB231, BT474, and SK-BR-3 using polymerase chain reaction PCR (Figure 7a), and we designed primers to uniquely amplify a sequence of 533 bp in its exon 18 (Table S3). Results show that high levels of FGFR1-238 were detected in cell lines MCF7, BT549, MB231, and BT474 (Figure 7a). Next, we designed five small interfering RNAs (siRNAs) that specifically target the unique coding sequence of FGFR1-238 (Table S4). Then we studied the dependence of tumor cell growth on the expression of FGFR1-238 by conducting a long-term (10 days) cell proliferation assay in the presence or absence (control) of siRNA knockdown. Our experimental results clearly show that the knockdown of the FGFR1-238 isoform inhibits the survival of MCF7 and BT549 cells (Figure 7b). Therefore, FGFR1 and especially its isoform FGFR1-238 could be promising targets for breast cancer therapy, implying the ability of AIDE in identifying full-length isoforms with biological functions in pathological conditions.

To further validate the specific biological function of isoform FGFR1-238, we also designed two siRNAs targeting two non-functional isoforms FGFR1-205 and FGFR1-C1 (novel) which were predicted by Cufflinks (Figure 7c, Table S4). The expressions of FGFR1-205 and FGFR1-C1 were validated in three breast cancer cell lines, BT549, MCF7, and BT474, by polymerase chain reaction PCR (Figure S12). The lengths of the amplified FGFR1-205 and FGFR1-C1 are 510 bp and 528 bp, respectively (Table S3). The three isoforms were knocked down in the host mammalian cells BT549, MCF7, and BT474 by RNA interference, respectively. The results of the colonegenic assay show that only the deletion of FGFR1-238 but not FGFR1-205 or FGFR1-C1 obviously impacted long term cell survival (Figure 7d). The isoform-specific function, which was only identified by AIDE in this case, further highlights the importance of alternative splicing
Figure 6: Experimental validation of isoforms predicted by AIDE and Cufflinks. Isoforms of genes \textit{MTHFD2} (a), \textit{NPC2} (b), \textit{RBM7} (c), \textit{CD164} (d), \textit{FGFR1} (e), and \textit{ZFAND5} (f) were validated by PCR and Sanger sequencing. The isoforms to validate (yellow) are listed under each gene (dark gray), with + / − indicating whether an isoform was / was not identified by PCR or a computational method. The forward (F) and reward (R) primers are marked on top of each gene. For each gene, the agarose gel electrophoresis result demonstrates the molecular lengths of PCR products, and the chromatography of Sanger sequencing confirms the sequences around the exon-exon junction unique to the PCR validated isoform.
Figure 7: **a**: PCR experiments validated the expression of *FGFR1-238* in breast cancer cell lines MCF7, SUM149, BT474, SK-BR-3, MB231, and BT549. **b**: Long-term colonegenic assay with lipo3000 controls ("siControl") and *FGFR1-238* knockdowns. Tumor growths relative to the siControl were quantified by the ImageJ software [44]. **c**: *FGFR1* isoforms identified by AIDE and Cufflinks. **d**: Long-term colonegenic assay with siControl (negative control), si-*FGFR1-238* (positive control), si-*FGFR1-205*, and si-*FGFR1-C1*. Tumor growths relative to the siControl were quantified by the ImageJ software.

Figure 8: *NRAS* isoforms predicted by AIDE, Cufflinks, and StringTie. *NRAS* isoforms in the GENCODE annotation, reported by Eisfeld et al. [45], and discovered by AIDE, Cufflinks, or StringTie in three melanoma BRAF inhibitor resistant cell lines: M229R, M263R, and M395R.
prediction.

To further compare AIDE and other reconstruction methods in identifying isoforms with biological functions, we applied AIDE, Cufflinks, and StringTie to the RNA-seq data of three melanoma cell lines. As one of the most predominant driver oncogenes, the tumorigenic function of NRAS was well described [46]. Recently, some novel isoforms of the gene NRAS were experimentally identified using quantitative PCR and shown to have potential roles in the cell proliferation and malignancy transformation [45]. Except for the canonical isoform 1, the other two isoforms identified by Eisfeld et al. have not been included in the GENCODE [8] or Ensembl [33] annotation (Figure 8). In our previous work, we profiled the transcriptomes of a serial of melanoma cell lines [47, 48]. We applied both AIDE and the other two reconstruction methods to the RNA-seq data of these cell lines. Our results showed that (1) two novel NRAS isoforms, in addition to the annotated isoform (isoform 1), were identified by AIDE; (2) only isoform 1 was identified in two out of the three cell lines by StringTie; 3) none of them was identified by Cufflinks (Figure 8). These results again demonstrate the potential of AIDE as a powerful bioinformatics tool for isoform discovery from short-read sequencing data.

**AIDE improves isoform abundance estimation on real data**

It would be ideal if we could evaluate the discovered isoforms and the estimated isoform abundance of different methods on real data. However, the structures and abundance of expressed isoforms are unobservable in real RNA-seq data. Therefore, we seek to evaluate the performance of different methods by comparing their estimated isoform expression levels in the FPKM unit with the NanoString counts, which could serve as benchmark data for isoform abundance when polymerase chain reaction (PCR) validation is not available [12, 49, 50, 51]. The NanoString nCounter technology is considered as one of the most reproducible and robust medium-throughput assays for quantifying gene and isoform expression levels [52, 53, 54]. We expect an accurate isoform discovery method to discover a set of isoforms close to the expressed isoforms in an RNA-seq sample. If the identified isoforms are accurate, the subsequently estimated isoform abundance is more likely to be accurate and agree better with the NanoString counts.

We therefore applied AIDE, Cufflinks, and StringTie to six samples of the human HepG2 (liver hepatocellular carcinoma) immortalized cell line with both RNA-seq and NanoString data [12] (Supplementary Table S1). We supplied all the three methods with the GENCODE annotation (version 24) [8] for their isoform discovery. SLIDE requires its input RNA-seq reads to have a unique read length after mapping and is thus not applicable to the six HepG2 mapped RNA-seq datasets. We note that the NanoString nCounter technology is not designed for genome-wide quantification of RNA molecules, and the HepG2 NanoString datasets have measurements of 140 probes corresponding to 470 isoforms of 107 genes. Since one probe may correspond to multiple isoforms, we first found the isoforms compatible with every probe, and we then compared the sum or the maximum of the estimated abundance of these isoforms with the count of that probe. For each HepG2 sample, we calculated the Spearman correlation coefficient between
Figure 9: Spearman correlation coefficients between the estimated isoform expression and the benchmark NanoString counts. 

a: For every probe, the sum of the expression levels of its corresponding isoforms is used in the calculation. 
b: For every probe, the maximum of the expression levels of its corresponding isoforms is used in the calculation.

the estimated isoform abundance (“sum” or “max”) and the NanoString probe counts to evaluate the accuracy of each method (Figure 9). AIDE has the highest correlations in five out of the six samples, suggesting that AIDE achieves more accurate isoform discovery as well as better isoform abundance estimation in this application. It is also worth noting that all three methods have achieved high correlation with the Nanostring counts for samples 3 and 4, since these two samples have the longest reads (100bp, Table S1) among all the samples. It is well acknowledged that long reads assist isoform identification by capturing more exon-exon junctions [51].

AIDE improves isoform discovery accuracy via stepwise selection

We also conducted a proof-of-concept simulation study to verify the efficiency and accuracy of our proposed AIDE method. We used this study to show why simply performing forward selection is insufficient and how stepwise selection leads to more precise and robust isoform discovery results. Here we considered 2,262 protein-coding genes from the human GENCODE annotation (version 24) [8]. We treated the annotated isoforms as the true isoforms and simulated paired-end RNA-seq reads from those isoforms with pre-determined abundance levels (Methods). For every gene, we applied AIDE, which uses stepwise selection, and its counterpart AIDEf, which only uses forward selection, to discover isoforms from the simulated reads. To evaluate the robustness of AIDE to the accuracy of annotation, we considered three types of annotation sets (details in Methods): (1) “N” (no) annotations: no annotated isoforms were used; (2) “I” (inaccurate) annotations: the “annotated isoforms” consisted of half of the randomly selected true isoforms and the same number of false isoforms; (3) “A” (accurate) annotations: the “annotated isoforms” consisted of half of the randomly selected true isoforms.

The simulation results averaged from the 2,262 genes show that AIDE and AIDEf perform the best when the “A” annotations are supplied, and they have the worst results with the “N”
annotations, as expected (Figure S13). Given the “A” annotations, AIDE and AIDEf have similarly good performance. However, when supplied with the “I” annotations and the “N” annotations, AIDE has much better performance than AIDEf. Notably, the performance of AIDE with the “I” annotations is close to that with the “A” annotations, demonstrating the robustness of AIDE to inaccurate annotations. On the other hand, AIDEf has decreased precision rates when the “I” annotations are supplied because forward selection is incapable of removing non-expressed annotated isoforms from its identified isoform set in stage 1 (Figure 1). Given the “N” annotations, AIDE also has better performance than AIDEf. These results suggest that choosing stepwise selection over forward selection is reasonable for AIDE because perfectly accurate annotations are usually unavailable in real scenarios.

Figure S13 also suggests that both approaches exhibit improved performance with all the three types of annotations as the read coverages increase. Higher read coverages help the most when the “N” annotations are supplied, but its beneficial effects become more negligible with the “A” annotations. When the coverages increase from 10x to 80x, the $F$ scores of AIDE increase by 32.6%, 12.3%, and 9.5% with the “N”, “I”, and “A” annotations, respectively. Moreover, we observe that the $F$ scores of AIDE with the “N” annotations and the 80x coverage are approximately 30% lower than the $F$ scores with the “A” annotations and the 30x coverage. This suggests that accurate annotations can assist isoform discovery and reduce the costs for deep sequencing depths to a large extent.

We also summarized the precision and recall rates of AIDE at the individual gene level (Figure S14). When the “A” annotations are supplied, both AIDE and AIDEf achieve 100% precision and recall rates for over 80% of the genes. When the “N” or “I” annotations are supplied, we observe a 2.0- or 2.6- fold increase in the number of genes with 100% precision and recall rates from AIDEf to AIDE. These results again demonstrate the effectiveness of AIDE in removing non-expressed annotated isoforms and identifying novel isoforms with higher accuracy due to its use of statistical model selection principles.

**Discussion**

We propose a new method AIDE to improve the precision of isoform discovery and the accuracy of isoform quantification from the next-generation RNA-seq data, by selectively borrowing alternative splicing information from annotations. AIDE iteratively identifies isoforms in a stepwise manner while placing priority on the annotated isoforms, and it performs statistical testing to automatically determine what isoforms to retain. We demonstrate the efficiency and superiority of AIDE compared to three state-of-the-art methods, Cufflinks, SLIDE, and StringTie, on multiple synthetic and real RNA-seq datasets followed by an experimental validation through PCR-Sanger sequencing, and the results suggest that AIDE leads to much more precise discovery of full-length RNA isoforms and more accurate isoform abundance estimation. In an evaluation based on the third-generation long-read RNA-seq data, AIDE also leads to the most consistent isoform
discovery results than the other methods do.

In addition to reducing false discoveries, AIDE is also demonstrated to identify full-length mRNA isoforms with biological significance in disease conditions. First, we assessed the biological significance of the isoform $FGFR1-238$, which was only identified by AIDE, using a loss-of-function assay. We selected six breast cancer samples that originally had this isoform expressed, and we experimentally proved that cell proliferation was inhibited with this isoform being knocked down. Second, we applied both AIDE and Cufflinks to RNA-seq data of melanoma cell lines for isoform discovery. Only AIDE was able to detect two novel isoforms of $NRAS$, which were reported to play a role in the drug resistance mechanism of BRAF-targeted therapy.

Even though long reads generated by PacBio and ONT have advantages over next-generation short RNA-seq reads for assembling full-length mRNA isoforms, it remains important and necessary to improve computational methods for short-read based isoform discovery. First, wide application of the long-read sequencing technologies is still hindered by their lower throughput, higher error rate, and higher cost per base [41]. Meanwhile, the next-generation short-read sequencing technology is still the mainstream assay for transcriptome profiling. Second, a huge number of next-generation RNA-seq datasets have been accumulated over the past decade. Considering that many biological or clinical samples used to generate those datasets are precious and no longer available for long-read sequencing, the existing short-read data constitute an invaluable resource for studying RNA mechanisms in these samples. Therefore, an accurate isoform discovery method will be indispensable for studying full-length isoforms from these data. Meanwhile, we also expect that with increased availability of long read data, we will be better equipped to compare and evaluate the reconstruction methods for short read data.

Due to technical limitations, the isoforms not amplified by PCR may still exist at an extremely low level. We attempted to reduce this possibility by optimizing the design and parameters used in our PCR experiments. First, we only validated the isoforms uniquely predicted by AIDE or Cufflinks if those isoforms have comparable abundance estimates (in FPKM unit). Hence, the PCR amplifications started with similar template amounts. Second, we designed the PCR primers to preferably amplify the isoforms predicted by Cufflinks (Table S3), so that if Cufflinks correctly identifies an isoform, the PCR experiment would capture it with high confidence. Specifically, when PCR primers are compatible with multiple isoforms of different lengths but similar abundance levels, PCR reaction preferentially amplifies the shorter isoform(s). Therefore, we experimentally validated the genes for which the isoform predicted by AIDE is longer than the isoform predicted by Cufflinks, and we designed the primers to be compatible with both isoforms. Third, we performed extensive amplification by setting the PCR cycle number to 50. Therefore, if an isoform is not captured by the PCR, it either does not exist or has extremely low abundance level. In either case, the isoform is not supposed to be biologically functional. Given the above considerations in experimental design and the validation results (Figure 6), we could safely draw the conclusion that AIDE has unique advantages in identifying full-length mRNA isoforms with a high precision and reducing false discoveries.
To the best of our knowledge, AIDE is the first isoform discovery method that identifies isoforms by selectively leveraging information from annotations based on a statistically principled model selection approach. The stepwise likelihood ratio testing procedure in AIDE has multiple advantages. First, AIDE only selects the isoforms that significantly contribute to the explanation of the observed reads, leading to more precise results and reduced false discoveries than those of existing methods. Second, the forward steps allow AIDE to start from and naturally give priority to the annotated isoforms, which have higher chances to be expressed in a given sample. Meanwhile, the backward steps allow AIDE to adjust its previously selected isoforms given its newly added isoform so that all the selected isoforms together better explain the observed reads. Third, the testing procedure in AIDE allows the users to adjust the conservatism and precision of the discovered isoforms according to their desired level of statistical significance. Because of these advantages, AIDE identifies fewer novel isoforms at a higher precision level than previous methods do, making it easier for biologists to experimentally validate the novel isoforms. In applications where the recall rate of isoform discovery is of great importance (i.e., the primary goal is to discover novel isoforms with a not-too-stringent criterion), users can increase the \( p \)-value threshold of AIDE to discover more novel isoforms.

Through the application of AIDE to multiple RNA-seq datasets, we demonstrate that selectively incorporating annotated splicing patterns, in addition to simply obtaining gene and exon boundaries from annotations, greatly helps isoform discovery. The stepwise selection in AIDE also differentiates it from the methods that directly assume the existence of all the annotated isoforms in an RNA-seq sample. The development and application of AIDE has lead us to interesting observations that could benefit both method developers and data users. First, we find that a good annotation can help reduce the need for deep sequencing depths. AIDE has been shown to achieve good accuracy on datasets with low sequencing depths when supplied with accurately annotated isoforms, and its accuracy is comparable to that based on deeply sequenced datasets. Second, we find it more important for an annotation to have high purity than to have high completeness, in order to improve the isoform discovery accuracy of AIDE and the other methods we compared with in our study. Ideally, instead of using all the annotated isoforms in isoform discovery tasks, a better choice is to use a filtered set of annotated isoforms with high confidence. This requires annotated isoforms to have confidence scores, which unfortunately are unavailable in most annotations. Therefore, how to add confidence scores to annotated isoforms becomes an important future research question, and answering this question will help the downstream computational prediction of novel isoforms.

In analysis tasks of discovering differential splicing patterns between RNA-seq samples from different biological conditions, a well-established practice is to first estimate the isoform abundance in each sample by using a method like Cufflinks, and then perform statistical testing to discover differentially expressed isoforms [55, 56]. However, as we have demonstrated in both synthetic and real data studies, existing methods suffer from high risks of predicting false positive isoforms, i.e., estimating non-zero expression levels for unexpressed isoforms in a sample. Such false
positive isoforms will severely reduce the accuracy of differential splicing analysis, leading to inaccurate comparison results between samples under two conditions, e.g., healthy and pathological samples. In contrast, AIDE’s conservative manner in leveraging the existing annotations allows it to identify truly expressed isoforms at a greater precision and subsequently estimate isoform abundance with a higher accuracy. We expect that the application of AIDE will increase the accuracy of differential splicing analysis, lower the experimental validation costs, and lead to new biological discoveries at a higher confidence level.

The probabilistic model in AIDE is very flexible and can incorporate reads of varying lengths and generated by different platforms. The non-parametric approach to learning the read generating mechanism makes AIDE a data-driven method and does not depend on specific assumptions of the RNA-seq experiment protocols. Therefore, a natural extension of AIDE is to combine the short but more accurate reads from the next-generation technologies with the longer but more error-prone reads generated by new sequencing technologies such as PacBio [41] and Nanopore [57]. Jointly modeling of the two types of reads using the AIDE method has the potential to greatly improve the overall accuracy of isoform detection [58], since AIDE is shown to have better precision than existing methods, and longer RNA-seq reads capture more splicing junctions and can further improve the recall rate of AIDE. Aside from the stepwise selection procedure used by AIDE, another possible way to incorporate priority on the annotated isoforms in the probabilistic model is to add regularization terms only on the unannotated isoforms. However, this approach is less interpretable compared with AIDE, since the regularization terms lack direct statistical interpretations as the $p$-value threshold does. Moreover, this approach may lose control of the false discovery rate when the annotation has a low purity. Another future extension of AIDE is to jointly consider multiple RNA-seq samples for more robust and accurate transcript reconstruction. It has been shown that it is often possible to improve the accuracy of isoform quantification by integrating the information in multiple RNA-seq samples [51, 59, 60]. Especially, using our previous method MSIQ we have demonstrated that it is necessary to account for the possible heterogeneity in the quality of different samples to improve the robustness of isoform quantification [51]. Therefore, by extending AIDE to combine the consistent information from multiple technical or biological samples, it is likely to achieve better reconstruction accuracy, and enable researchers to integrate publicly available and new RNA-seq samples for transcriptome studies.

Methods

Isoform discovery and abundance estimation using AIDE

The AIDE method is designed to identify and quantify the mRNA isoforms of an individual gene. Suppose that a gene has $m$ non-overlapping exons and $J$ candidate isoforms. If no filtering steps based on prior knowledge or external information is applied to reduce the set of candidate isoforms, $J$ equals $2^m - 1$, the number of all possible combinations of exons into isoforms. The
observed data are the $n$ RNA-seq reads mapped to the gene: $R = \{r_1, \ldots, r_n\}$. The parameters we would like to estimate are the isoform proportions $\alpha = (\alpha_1, \ldots, \alpha_J)'$, where $\alpha_j$ is the proportion of isoform $j$ among all the isoforms (i.e., the probability that a random RNA-seq read is from isoform $j$) and $\sum_{j=1}^{J} \alpha_j = 1$. We also introduce hidden variables $Z = \{Z_1, \ldots, Z_n\}$ to denote the isoform origins of the $n$ reads, with $Z_i = j$ indicating that read $r_i$ is from isoform $j$, and $P(Z_i = j) = \alpha_j$, for $i = 1, \ldots, n$.

The joint probability of read $r_i$ and its isoform origin can be written as:

$$P(r_i, Z_i | \alpha) = \prod_{j=1}^{J} P(r_i, Z_i = j | \alpha) I\{Z_i = j\}$$

$$= \prod_{j=1}^{J} [P(r_i | Z_i = j) \alpha_j] I\{Z_i = j\}$$

$$= \prod_{j=1}^{J} (h_{ij} \alpha_j) I_{ij},$$

where $I_{ij} \triangleq I\{Z_i = j\}$ indicates whether read $r_i$ is from isoform $j$, and $h_{ij} \triangleq P(r_i | Z_i = j)$ is the generating probability of read $r_i$ given isoform $j$, calculated based on the read generating mechanism described in the following subsection.

**Read generating mechanism**

We have defined $h_{ij}$ as the generating probability of read $r_i$ given isoform $j$. Specifically, if read $r_i$ is not compatible with isoform $j$ (read $r_i$ contains regions not overlapping with isoform $j$, or vice versa), then $h_{ij} = 0$; otherwise,

$$h_{ij} = P(\text{starting position of read } r_i \mid \text{isoform } j) P(\text{fragment length of read } r_i \mid \text{isoform } j)$$

$$\triangleq P_{ij}^s P_{ij}^f.$$

In the literature, different models have been used to calculate the starting position distribution $P^s$ and the fragment length distribution $P^f$. Most of these models are built upon a basic model:

$$P_{ij}^s = \frac{1}{L_j},$$

$$P_{ij}^f = \frac{1}{\sqrt{2\pi}\sigma_f} \exp \left\{ -\frac{(l_{ij} - \mu_f)^2}{2\sigma_f^2} \right\},$$

where $L_j$ is the effective length of isoform $j$ (the isoform length minus the read length), and $l_{ij}$ is the length of fragment $i$ given that read $r_i$ comes from isoform $j$. However, this basic model does not account for factors like the GC-content bias or the positional bias (see Introduction). Research has shown that these biases affect read coverages differently, depending on different experimental protocols. For example, reverse-transcription with poly-dT oligomers results in an
over-representation of reads in the 3’ ends of isoforms, while reverse-transcription with random hexamers results in an under-representation of reads in the 3’ ends of isoforms [61]. Similarly, different fragmentation protocols have varying effects on the distribution of reads within an isoform [24].

Given these facts, we decide to use a non-parametric method to estimate the distribution $P_s$ of read starting positions, because non-parametric estimation is intrinsically capable of accounting for the differences in the distribution due to different protocols. We use a multivariate kernel regression to infer $P_s$ from the reads mapped to the annotated single-isoform genes. Suppose there are a total of $c_s$ exons in the single-isoform genes. For $k' = 1, \ldots, c_s$, we use $q_{k'}$ to denote the proportion of reads, whose starting positions are in exon $k'$, among all the reads mapped to the gene containing exon $k'$. Given any gene with $J$ isoforms, suppose there are $c_j$ exons in its isoform $j$, $j = 1, \ldots, J$. We estimate the conditional probability that a (random) read $r_i$ starts from exon $k$ ($k = 1, 2, \ldots, c_j$), given that the read is generated from isoform $j$, as:

$$
P_{ij}^s(b_i = k) \propto \sum_{k'=1}^{c_s} \prod_{d=1}^{3} \frac{1}{h_d} K \left( \frac{x_{kd} - x_{k'd}}{h_d} \right) q_{k'}, \quad \text{such that} \quad \sum_{k=1}^{c_j} P_{ij}^s(b_i = k) = 1, \tag{1}
$$

where $b_i$ denotes the (random) index of the exon containing the starting position of the read $r_i$. When $b_i = k$, we use $x_{k1}$, $x_{k2}$, and $x_{k3}$ to denote the GC content, the relative position, and the length of exon $k$, respectively. The GC content of exon $k$, $x_{k1}$, is defined as the proportion of nucleotides G and C in the sequence of exon $k$. The relative position of exon $k$, $x_{k2}$, is calculated by first linearly mapping the genomic positions of isoform $j$ to $[0, 1]$ (i.e., the start and end positions are mapped to 0 and 1 respectively) and then locating the mapped position of the center position of the exon. For example, if isoform $j$ spans from position 100 to position 1100 in a chromosome, and the center position of the exon is 200 in the same chromosome, then the relative position of this exon is 0.1. The meaning of $x_{k'd}$ ($k' = 1, \ldots, c_s; d = 1, \ldots, 3$) are be defined in the same way. The kernel function $K(\cdot)$ is set as the Gaussian kernel $K(x) = \frac{1}{\sqrt{2\pi}} \exp(-x^2)$. $h_d$ denotes the bandwidth of dimension $d$ and is selected by cross validation. The whole estimation procedure of $P_{ij}^s$ is implemented through the R package np.

As for the fragment length distribution $P_f$, we assume that it follows a truncated log normal distribution. This is because mRNA fragments that are too long or too short are filtered out in the library preparation step before the sequencing step. In addition, the empirical fragment length distribution is usually skewed to right instead of being symmetric (Figure S1). Therefore, a truncated log normal distribution generally fits well the empirical distribution of fragment lengths:

$$
P_{ij}^f = \begin{cases} 
\sqrt{2} \exp \left( - \left[ \log \left( \frac{l_{ij}}{t_f} \right) \right]^2 / 2\sigma_f^2 \right), & \text{if } l_{ij} \in [t_f^l, t_f^u], \\
\sqrt{\pi} \sigma_f \left[ \text{erf} \left( \frac{1}{\sqrt{2}\sigma_f} \log \left( \frac{l_{ij}}{t_f} \right) \right) - \text{erf} \left( \frac{1}{\sqrt{2}\sigma_f} \log \left( \frac{t_f^l}{t_f} \right) \right) \right], & \text{if } l_{ij} \in [t_f^l, t_f^u], \\
0, & \text{otherwise}
\end{cases} \tag{2}
$$
where \( m_f \) and \( \sigma_f \) are the median and the shape parameter of the distribution, respectively; \( t_f^l \) is the lower truncation threshold, and \( t_f^u \) is the upper truncation threshold. The function \( \text{erf}(\cdot) \) (the "error function" encountered in integrating the normal distribution) is defined as \( \text{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x \exp(-t^2) dt. \)

**The probabilistic model and parameter estimation in AIDE**

Given the aforementioned settings, the joint probability of all the observed and hidden data is

\[
P(R, Z | \alpha) = \prod_{i=1}^{n} P(r_i, Z_i | \alpha) = \prod_{i=1}^{n} \prod_{j=1}^{J} (h_{ij} \alpha_j)^{I_{ij}} = \prod_{i=1}^{n} \prod_{j=1}^{J} (P_{ij}^s P_{ij}^f \alpha_j)^{I_{ij}},
\]

where \( P_{ij}^s \) and \( P_{ij}^f \) are defined in Equations (1) and (2), and the complete log-likelihood is

\[
\ell(\alpha | R, Z) = \sum_{i=1}^{n} \sum_{j=1}^{J} I_{ij} \log \left( P_{ij}^s P_{ij}^f \alpha_j \right).
\]  

(3)

However, as \( Z \) and the resulting \( I_{ij} \)'s are unobservable, the problem of isoform discovery becomes to estimate \( \alpha \) via maximizing the log-likelihood based on the observed data:

\[
\hat{\alpha} = \arg \max_{\alpha} \ell(\alpha | R) = \arg \max_{\alpha} \log P(R | \alpha) = \arg \max_{\alpha} \log \left( \prod_{i=1}^{n} \left( \sum_{j=1}^{J} P_{ij}^s P_{ij}^f \alpha_j \right) \right) = \arg \max_{\alpha} \sum_{i=1}^{n} \log \left( \sum_{j=1}^{J} P_{ij}^s P_{ij}^f \alpha_j \right),
\]

(4)

subject to \( \alpha_j \geq 0 \) and \( \sum_{j=1}^{J} \alpha_j = 1 \). To directly solve (4) is not easy, so we use on the expectation-maximization (EM) algorithm along with the complete log-likelihood (3), and it follows that we can iteratively update the estimated isoform proportions as

\[
\alpha_j^{(t+1)} = \frac{1}{n} \sum_{i=1}^{n} \frac{P_{ij}^s P_{ij}^f \alpha_j^{(t)}}{\sum_{j'=1}^{J} P_{ij}^s P_{ij'}^f \alpha_j^{(t)}}.
\]
As the algorithm converges, we obtain the estimated isoform proportion $\hat{\alpha} = (\hat{\alpha}_1, \ldots, \hat{\alpha}_J)'.

**Stepwise selection in AIDE**

If we directly consider all the $J = 2^m - 1$ candidate isoforms in formula (4) and calculate $\hat{\alpha}$, the problem is unidentifiable when $J > n$. Even when $J \leq n$, this may lead to many falsely discovered isoforms whose $\hat{\alpha}_j > 0$, especially for complex genes, because the most complex model with all the possible candidate isoforms would best explain the observed reads. Therefore, instead of directly using the EM algorithm to maximize the log-likelihood with all the possible candidate isoforms, we perform a stepwise selection of isoforms based on the likelihood ratio test (LRT). This approach has two advantages. On the one hand, we can start from a set of candidate isoforms with high confidence based on prior knowledge, and then we can sequentially add new isoforms to account for reads that cannot be fully explained by existing candidate isoforms. For example, a common case is to start with annotated isoforms. On the other hand, the stepwise selection by LRT intrinsically introduce sparsity into the isoform discovery process. Even though the candidate isoform pool can be huge when a gene has a large number of exons, the set of expressed isoforms is usually much smaller in a specific biological sample. LRT can assist us in deciding a termination point where adding more isoforms does not further improve the likelihood.

The stepwise selection consists of steps with two opposite directions: the forward step and the backward step (Figure 1). The forward step aims at finding a new isoform to best explain the RNA-seq reads and significantly improve the likelihood given the already selected isoforms. The backward step aims at rectifying the isoform set by removing the isoform with the most trivial contribution among the selected isoforms. Since stepwise selection is in a greedy-search manner, some forward steps, especially those taken in the early iterations, may not be the globally optimal options. Therefore, backward steps are necessary to correct the search process and result in a better solution path for the purpose of isoform discovery.

We separate the search process into two stages. We use stepwise selection to update the identified isoforms at both stages, but the initial isoform sets and the candidate sets are different in the two stages. Stage 1 starts with a single annotated isoforms that explains the most number of reads, and it considers all the annotated isoforms as the candidate isoforms. Stage 1 stops when the forward step can no longer finds an isoform to add to the identified isoform set, i.e., the LRT does not reject the null hypothesis given the $p$-value threshold. Stage 2 starts with the isoforms identified in stage 1, and considers all the possible isoforms, including the annotated isoforms not chosen in stage 1, as the candidate isoforms (Figure 1). The initial isoform set is denoted as $S_1^{(0)}$ (stage 1) or $S_2^{(0)}$ (stage 2), the candidate isoform set is denoted as $C_1$ (stage 1) or $C_2$ (stage 2), and the annotation set is denoted as $A$. At stage 1, the initial set and candidate
set are respectively defined as
\[ S^{(0)}_1 = \left\{ \arg\max_{j \in A} (\text{number of reads compatible with isoform } j) \right\}, \]
\[ C_1 = A. \]

Suppose the stepwise selection completes after \( t_1 \) steps in stage 1, and the estimated isoform proportions after step \( t \) (\( t = 1, 2, \ldots, t_1 \)) are denoted as \( \hat{\alpha}^{(t)} = (\hat{\alpha}_1^{(t)}, \ldots, \hat{\alpha}_J^{(t)})' \). Note that \( \forall j \notin C_1, \hat{\alpha}_j^{(t)} = 0 \) in stage 1. At stage 2, the initial set and the candidate set are respectively defined as
\[ S^{(0)}_2 = \left\{ j : \hat{\alpha}_j^{(t_1)} > 0 \right\}, \]
\[ C_2 = \{1, 2, \ldots, J = 2^m - 1\}. \]

Here we introduce how to perform forward and backward selection based on a defined initial isoform set \( S^{(0)} \) and a candidate set \( C \). We ignore the stage number subscripts for notation simplicity. At both stages, we first estimate the expression levels of the initial isoform set \( S^{(0)} \):
\[ \hat{\alpha}^{(0)} = \arg\max_{\alpha} \ell (\alpha | R) = \arg\max_{\alpha} \sum_{i=1}^{n} \log \left( \sum_{j \in S^{(0)}} P_{ij}^s P_{ij}^f \alpha_j \right), \]
subject to \( \alpha_j \geq 0 \) if \( j \in S^{(0)} \), \( \alpha_j = 0 \) if \( j \notin S^{(0)} \), and \( \sum_{j \in S^{(0)}} \alpha_j = 1 \), based on the EM algorithm.

**Forward step**

The identified isoform set at step \( t \) is denoted as \( S^{(t)} = \{ j : \hat{\alpha}_j^{(t)} > 0 \} \). The log-likelihood at step \( t \) is
\[ \ell^{(t)} = \ell (\hat{\alpha}^{(t)} | R) = \sum_{i=1}^{n} \log \left( \sum_{j \in S^{(t)}} P_{ij}^s P_{ij}^f \hat{\alpha}_j^{(t)} \right). \]

At step \((t + 1)\), we consider adding one isoform \( k \in C \setminus S^{(t)} \) into \( S^{(t)} \) as a forward step. Given \( S^{(t)} \) and \( k \), we estimate the corresponding isoform proportions as
\[ \hat{\alpha}^{(t,k)} = \arg\max_{\alpha} \sum_{i=1}^{n} \log \left( \sum_{j \in S^{(t)} \cup \{k\}} P_{ij}^s P_{ij}^f \hat{\alpha}_j^{(t)} \right), \]
subject to \( \alpha_j \geq 0 \) if \( j \in S^{(t)} \cup \{k\} \), and \( \alpha_j = 0 \) otherwise. Then we choose the isoform
\[ k^* = \arg\max_{k} \sum_{i=1}^{n} \log \left( \sum_{j \in S^{(t)} \cup \{k\}} P_{ij}^s P_{ij}^f \hat{\alpha}_j^{(t,k)} \right), \]
which maximizes the likelihood among all the newly added isoforms. Then the log-likelihood with the addition of this isoform $k^*$ becomes

$$\ell^* = \sum_{i=1}^{n} \log \left( \sum_{j \in S^{(t)\cup\{k^*\}}} P_{ij}^s P_{ij}^f \hat{\alpha}_j^{(t,k^*)} \right).$$

To decide whether to follow the forward step and add isoform $k^*$ the identified isoform set, we use a likelihood ratio test (LRT) to test the null hypothesis ($H_0: S^{(t)}$ is the true isoform set from which the RNA-seq reads were generated) against the alternative hypothesis ($H_a: S^{(t)} \cup \{k^*\}$ is the true isoform set). Under $H_0$ we asymptotically have

$$-2(\ell(t) - \ell^*) \sim \chi^2(1).$$

If the null hypothesis is rejected at a pre-specified significance level (i.e., $p$-value threshold), then $S^{(t+1)} = S^{(t)} \cup \{k^*\}$, $\hat{\alpha}^{(t+1)} = \hat{\alpha}^{(t,k^*)}$, and the log-likelihood is updated as

$$\ell^{(t+1)} = \sum_{i=1}^{n} \log \left( \sum_{j \in S^{(t+1)}} P_{ij}^s P_{ij}^f \hat{\alpha}_j^{(t+1)} \right).$$

Otherwise, $S^{(t+1)} = S^{(t)}$, $\hat{\alpha}^{(t+1)} = \hat{\alpha}^{(t)}$, and $\ell^{(t+1)} = \ell^{(t)}$.

**Backward step**

Every time we add an isoform to the identified isoform set in a forward step (say the updated isoform set is $S^{(t+1)}$), we subsequently consider possibly removing one isoform $k \in S^{(t+1)}$ from $S^{(t+1)}$ in a backward step. Given $S^{(t+1)}$ and $k$, we estimate the corresponding isoform proportions as

$$\hat{\alpha}^{(t+1),-k} = \arg\max_{\alpha} \sum_{i=1}^{n} \log \left( \sum_{j \in S^{(t+1)} \setminus \{k\}} P_{ij}^s P_{ij}^f \alpha_j \right),$$

subject to $\alpha_j \geq 0$ if $j \in S^{(t+1)} \setminus \{k\}$, and $\alpha_j = 0$ otherwise. Then we choose the isoform

$$k^- = \arg\max_k \sum_{i=1}^{n} \log \left( \sum_{j \in S^{(t+1)} \setminus \{k\}} P_{ij}^s P_{ij}^f \hat{\alpha}_j^{(t+1),-k} \right),$$

which maximizes the likelihood among all the isoforms in $S^{(t+1)}$. Then the log-likelihood with the removal of this isoform $k^-$ becomes

$$\ell^- = \sum_{i=1}^{n} \log \left( \sum_{j \in S^{(t+1)} \setminus \{k^-\}} P_{ij}^s P_{ij}^f \hat{\alpha}_j^{(t+1),-k^-} \right).$$
To decide whether to follow the forward step and remove isoform $k^-$ from the identified isoform set, we use a likelihood ratio test (LRT) to test the null hypothesis ($H_0 : S^{(t+1)} \setminus \{k^-\}$ is the true isoform set from which the RNA-seq reads were generated) against the alternative hypothesis ($H_a : S^{(t+1)}$ is the true isoform set). Under $H_0$ we asymptotically have

$$-2(l - l^{(t+1)}) \sim \chi^2(1).$$

If the null hypothesis is not rejected at a pre-specified significance level (i.e., $p$-value threshold), then $S^{(t+2)} = S^{(t+1)} \setminus \{k^-\}$, $\hat{\alpha}^{(t+2)} = \hat{\alpha}^{(t+1), -k^-}$, and the log-likelihood is updated as

$$\ell^{(t+2)} = \sum_{i=1}^{n} \log \left( \sum_{j \in S^{(t+2)}} P_{ij} P_{ij}^{f} \hat{\alpha}^{(t+2)}_{j} \right).$$

Otherwise, $S^{(t+2)} = S^{(t+1)}$, $\hat{\alpha}^{(t+2)} = \hat{\alpha}^{(t+1)}$, and $\ell^{(t+2)} = \ell^{(t+1)}$.

In both stage 1 and stage 2, we iteratively consider the forward step and backward step and stop the algorithm at the first time when a forward step no longer adds an isoform to the identified set (Figure 1). To determine whether to reject a null hypothesis in a LRT, we set a threshold on the $p$-value. The default threshold is $0.01$. Unlike the thresholds set on the FPKM values or isoform proportions in other methods, this threshold on $p$-values allow users to tune the AIDE method based on their desired level of statistical significance. A larger threshold generally leads to more discovered isoforms and a better recall rate, while a smaller threshold leads to fewer discovered isoforms that are more precise.

**Simulation for comparing isoform reconstruction methods**

We considered 18,960 protein-coding genes from the human GENCODE annotation (version 24) [8]. For each gene, we set the proportions of isoforms not in the GENCODE database to 0. As for the annotated isoforms in GENCODE, their isoform proportions were simulated from a symmetric Dirichlet distribution with parameters $(1/\lceil J/2 \rceil, \ldots, 1/\lceil J/2 \rceil)'$, where $J$ denotes the number of annotated isoforms for a given gene. When simulating the RNA-seq reads, we treated these simulated proportions as the pre-determined ground truth. Next, for each target read coverage among the eight choices (10x, 20x, . . . , 80x), we used the R package polyester to simulate one RNA-seq sample given the pre-determined isoform proportions. All the simulated RNA-seq samples contained paired-end reads with 100 bp length.
Long read data processing

In the comparison with the long-read sequencing technologies, the isoforms were identified by Weirather et al. [43] based on the long reads generated using the ONT or PacBio technologies. In summary, the long reads were first processed using the SMRT software (https://www.pacb.com/products-and-services/analytical-software/smrt-analysis/; for PacBio) or the poretools software (https://poretools.readthedocs.io/en/latest/; for ONT). Then the reads were aligned and full-length transcripts were identified using the AlignQC software (https://www.healthcare.uiowa.edu/labs/au/AlignQC/). Please refer to Weirather et al. for details.

Transcriptome profiling by next-generation sequencing

Breast cancer biopsies were collected from Clinical Research Center for Breast of West China Hospital under the supervision of China Association for Ethical Studies. The whole-transcriptome RNA sequencing was performed with the next-generation sequencing standard protocol using the sequencer Solexa (Illumina). Long RNA sequences were first converted into a library of cDNA fragments, and adapters were subsequently added to each cDNA fragment. Solexa relies on the attachment of small DNA fragments to a platform, optically transparent surface, and solid-phase amplification to create an ultrahigh-density sequencing flow cell with >10 million clusters, each containing \(\sim 1,000\) copies of template/cm\(^2\). These templates were sequenced by a robust four-color DNA sequencing-by-synthesis technology that employs reversible terminators with removable fluorescence. The high-sensitivity fluorescence was then detected by laser excitation. The typical output from a single reaction was approximately 2GB containing 20-40 million reads. The Solexa-sequenced reads were assembled using the CLC bio software. Before the assembly, the reads were preprocessed by masking the polyA tails and removing the adapters.

Validation of transcripts by PCR and Sanger sequencing

Biopsy was collected freshly and the total RNA was extracted with the RiboPure Kit (Ambion). The reverse transcription reactions were performed using the RevertAid First-Strand cDNA Synthesis System kit (ThermoFisher). With the cDNAs as templates and primers from TSINGKE, the PCR procedure (95°C 5min, 95°C 30s, 55°C 30s, 72°C 1min to 2min, 40 to 50 cycles, 72°C 5min for extension) was conducted using a ThermoFisher PCR system. PCR products were purified using Gel Extraction Kit (OMEGA) followed by Sanger sequencing with their special forward primers. Finally, sequencing result was analyzed using the Sequence Scanner Software.

Validation of isoform functions by colonic assay

Breast cancer cell lines BT549, MB231, SUM149, BT474, SK-BR-3, and MCF-7 were from ATCC and cultured in the State Key Laboratory of Biotherapy. The cells’ total RNA was extracted with the RiboPure Kit (Ambion), and the reverse transcription reactions were performed using the
RevertAid First-Strand cDNA Synthesis System kit (ThermoFisher). With the cDNAs as templates and primers from TSINGKE, the PCR procedure (95°C 5min, 95°C 30s, 55°C 30s, 72°C 1min, 40 cycles, 72°C 5min for extension) was conducted using a ThermoFisher PCR system. PCR products were purified using the Gel Extraction Kit (OMEGA) followed by Sanger sequencing with special forward primers. The five siRNAs specifically targeting \textit{FGFR1-238} were synthesized at Shanghai GenePharma. Lipofactamin3000 from Invitrogen were used in siRNA transferring in breast cancer cells on the first day and the sixth day. The cells’ colonogenic assays lasted for 10-12 days.

\textbf{Proof-of-concept simulation strategy}

To evaluate the robustness of AIDE to the accuracy of annotation, we considered three types of annotation sets: (1) “N” (no) annotations: no annotated isoforms were used, and both AIDE and AIDEf were initialized with the candidate isoform compatible with the most reads and directly went into stage 2 (Figure 1); (2) “I” (inaccurate) annotations: the “annotated isoforms” used in stage 1 (Figure 1) consisted of half of the randomly selected true isoforms and the same number of false isoforms (not in the GENCODE annotation but randomly assembled from exons); (3) “A” (accurate) annotations: the “annotated isoforms” used in stage 1 (Figure 1) consisted of half of the randomly selected true isoforms. We generated RNA-seq data with different read coverages to compare AIDE and AIDEf with each of the three types of annotations, and we evaluated the performance of AIDE and AIDEf in terms of the precision rate, the recall rate, and the $F$ score.

We consider 2,262 protein-coding genes from the human GENCODE annotation (version 24) [8]. The exon numbers of these genes range from 2 to 10. We treat the annotated isoforms in this GENCODE annotation as the true isoforms, randomly assign isoform abundance, and simulate paired-end RNA-seq reads from those isoforms with a 100 bp read length. As we know the underlying true isoforms and their abundance in this simulation, we can use them to evaluate the accuracy of AIDE.

Suppose that gene $i$ has $J_i$ annotated isoforms in the GENCODE annotation. We assume these $J_i$ isoforms are the true isoforms, and we randomly select from them $\lceil \frac{J_i}{2} \rceil$ isoforms to be used in the “A” annotations or the “I” annotations. The isoform proportions of the true isoforms are simulated from a symmetric Dirichlet distribution with parameters $\left(1/\left\lceil \frac{J_i}{2} \right\rceil, \ldots, 1/\left\lceil \frac{J_i}{2} \right\rceil\right)'$. The total number of reads generated from gene $i$ depends on the gene length and the read coverage. Within each transcript, the starting positions of reads are uniformly distributed, and the fragment length follows a log-normal distribution with mean 180 bp and standard deviation 65 bp. Once we simulate the reads, we find the chromosome coordinates of the two ends of each read, and those coordinates are the only observed data input into AIDE and AIDEf.
Software Availability

The AIDE method has been implemented in the R package AIDE, which is publicly available at https://github.com/Vivianstats/AIDE.

We carried out our analysis using the Cufflinks software v2.2.1, the StringTie software v1.3.3b, the SLIDE software, and the AIDE package v0.0.2. As an example of computational efficiency, we analyzed the hESC Illumina RNA-seq sample (containing around 167.5 million paired-end reads) using the Ubuntu 14.04.5 system and 2 CPUs of Intel(R) Xeon(R) CPU E5-2687W v4 @ 3.00GHz. Using 12 cores, the running time of Cufflinks, StringTie, and AIDE was 1,440 minutes, 195 minutes, and 410 minutes, respectively. The memory usage of Cufflinks, StringTie, and AIDE was 17G, 8G, and 25G, respectively.

**Calculation of precision and recall rate of isoform reconstruction**

We denote the true isoform set in an RNA-seq sample as $S$ and the discovered isoform set as $D$. We use $B(s)$ and $E(s)$ to denote the number of bases and the number of exons in isoform $s$, respectively. We calculate the isoform-level precision and recall rate of isoform discovery by comparing the two sets $S$ and $D$. When compare the isoform $s_1$ in $S$ and $s_2$ in $D$, we allow a small difference by requiring the number of mismatch bases to be smaller than $0.99B(s_1)$. The isoform-level precision and recall rates are calculated as

$$\text{precision}^{\text{isoform}} = \frac{|D \cap S|}{|D|}, \quad \text{recall}^{\text{isoform}} = \frac{|D \cap S|}{|S|}.$$ 

The exon-level precision and recall rates are calculated as

$$\text{precision}^{\text{exon}} = \frac{\sum_{s \in D \cap S} E(s)}{\sum_{s \in D} E(s)}, \quad \text{recall}^{\text{exon}} = \frac{\sum_{s \in D \cap S} E(s)}{\sum_{s \in S} E(s)}.$$ 

The base-level precision and recall rates are calculated as

$$\text{precision}^{\text{base}} = \frac{\sum_{s \in D \cap S} B(s)}{\sum_{s \in D} B(s)}, \quad \text{recall}^{\text{base}} = \frac{\sum_{s \in D \cap S} B(s)}{\sum_{s \in S} B(s)}.$$

Figure S1: The distribution of fragment lengths in real RNA-seq data. The empirical fragment length distribution of four example mouse genes in the mouse bone marrow-derived macrophage dataset (Table S1).
**Figure S2:** Distributions of per-gene precision rates of AIDE and the other three isoform discovery methods in simulation. Each box gives the 1st quantile, median, and 3rd quantile of the per-gene precision rates given the corresponding synthetic annotation set and read coverage.
Figure S3: Distributions of per-gene recall rates of AIDE and the other three isoform discovery methods in simulation. Each box gives the 1st quantile, median, and 3rd quantile of the per-gene recall rates given the corresponding synthetic annotation set and read coverage.
Figure S4: Isoform discovery for the human gene *DPM1* with the synthetic annotation set 1. The histogram and the sashimi plot denote the RNA-seq reads mapped to the gene *DPM1* in the RNA-seq data simulated by the *polyester* R package. The annotation (white) for this gene has a 67% purity and a 67% completeness, compared with the truly expressed isoforms (yellow). AIDE, Cufflinks, and StringTie each discovers three isoforms, but only AIDE is able to identify the shortest isoform missing in the annotation. SLIDE reports 17 isoforms, which are not displayed in the plot.
Figure S5: Isoform discovery for the human gene *DPM1* with the synthetic annotation set 9. The histogram and the sashimi plot denote the RNA-seq reads mapped to the gene *DPM1* in the RNA-seq data simulated by the polyester R package. The annotation (white) for this gene has a 60% purity and a 100% completeness, compared with the truly expressed isoforms (yellow). AIDE, Cufflinks, and StringTie respectively discovers three, five, and four isoforms, and only AIDE is able to identify the three true isoforms with 100% accuracy. SLIDE reports 20 isoforms, which are not displayed in the plot.
**Figure S6:** Comparison between AIDE and the other three isoform discovery methods in simulation. What is displayed is the genome-wide average performance of AIDE, Cufflinks, StringTie, and SLIDE given each of the nine synthetic annotation sets. The base-level, exon-level, and isoform-level precision rates, recall rates, and $F$ scores averaged across the human genes are calculated based on RNA-seq data with a 10x coverage.
Figure S7: Comparison between AIDE and the other three isoform discovery methods in real data studies. We applied AIDE, Cufflinks, StringTie, and SLIDE to isoform discovery on three human ESC samples (a) and three mouse macrophage samples (b). The estimated expression levels of the predicted isoforms were then summarized in the FPKM unit. The precision-recall curves (at isoform-level) were obtained by thresholding the FPKM values of the predicted isoforms. The corresponding AUC of each method is also marked in the plot.
Figure S8: Isoform discovery for the human genes ZBTB11 and TOR1A based on real data. The histogram and the sashimi plot denote the RNA-seq reads mapped to the two genes in the human ESC sample 1 (Table S1). Isoform discovery is based on the GENCODE human annotation version 24. AIDE achieves the best accuracy among the four methods.
Figure S9: Isoform discovery for the human genes MALSU1 and SRSF6 based on real data. The histogram and the sashimi plot denote the RNA-seq reads mapped to the two genes in the human ESC sample 1 (Table S1). Isoform discovery is based on the GENCODE human annotation version 24. AIDE achieves the best accuracy among the four methods.
Figure S10: Isoform discovery for the human genes ZBTB11 and TOR1A given different p-value thresholds. The histogram and the sashimi plot denote the RNA-seq reads mapped to the two genes in the human ESC sample 1 (Table S1). Isoform discovery is based on the GENCODE human annotation version 24. The threshold on the p-values resulted from the likelihood ratio tests decreases from $10^{-2}$ to $10^{-10}$. 

53
Figure S11: Isoform discovery for the human genes \textit{MALSU1} and \textit{SRSF6} given different $p$-value thresholds. The histogram and the sashimi plot denote the RNA-seq reads mapped to the two genes in the human ESC sample 1 (Table S1). Isoform discovery is based on the GENCODE human annotation version 24. The threshold on the $p$-values resulted from the likelihood ratio tests decreases from $10^{-2}$ to $10^{-10}$. 
**Figure S12:** The expression of *FGFR1-205* and *FGFR1-C1* in breast cancer cell lines MCF7, BT474, and BT549 were validated by PCR.

**Figure S13:** Comparison of AIDE (stepwise selection) and AIDEf (forward selection only) in terms of the average $F$ scores, precision rates, and recall rates (i.e., three measures) across the 2,262 genes in simulation. For AIDE and AIDEf, each measure is calculated based on three types of annotations and RNA-seq samples with varying read coverages. The vertical axes of the three panels denote the values of the three measures, and the horizontal axis denotes the average per-base coverage of RNA-seq reads.
Figure S14: Comparison of AIDE (stepwise selection) and AIDEf (forward selection only) in terms of the per-gene precision and recall rates in simulation, with 80x read coverage and three types of annotations. The circle sizes are proportional to the proportions of genes with the corresponding precision and recall rates, with the top-right circles indicating 100% accuracy.
